Figure 2 Comparison between a bird-maintained zoonotic virus (such as the St. Louis encephalitis virus) and an anthroponotic virus (such as dengue virus). Activities to decrease or interrupt virus amplification and thereby prevent human cases.

to major epidemics (transmission to or among humans). The distinction between zoonoses and anthroponoses becomes blurred with viruses such as yellow fever virus, in which there is a distinct enzootic primate–mosquito–primate maintenance cycle in jungle habitats and then an epidemic human–mosquito–human cycle in urban habitats.

Factors Enabling Transmission

The efficiency of arbovirus transmission depends upon genetic factors that encode for susceptibility to infection and for biological traits that enable vector survival and repeated susceptible host contact. These properties may be summarized, respectively, as vector competence and vectorial capacity.

Vector Competence

The innate ability of an arthropod to acquire and transmit an arbovirus is termed vector competence. Infection occurs when the ingested virus binds to receptor sites in the lumen of the midgut of the vector and then enters the midgut cells. Susceptibility to infection typically relates to the number of receptor sites and to the affinity of the infecting virus to bind with these sites. Many arthropods lack suitable binding sites, do not get infected, and have what is termed a midgut infection barrier. Others allow midgut infection and perhaps low-level virus replication, but the infection remains midgut-limited and does not disseminate to infect the salivary glands. Post-transcriptional gene silencing by RNA interference (RNAi) is a natural antiviral response in mosquitoes. As a countermeasure, some arboviruses evade RNAi or produce RNAi suppressors that limit antiviral defense. These viruses replicate to high levels and escape the midgut; however, not all infect the salivary glands or they infect the salivary glands but are not transmitted. These salivary gland barriers may be similar to midgut infection and escape barriers and are referred to as salivary gland infection and escape barriers. Still other less-known vector attributes may downregulate infections after or during dissemination, also limiting transmission. In these vectors, transmission peaks soon after infection, but then decreases over time, so that older vectors have lower transmission rates than younger vectors. In general, however, competent vectors frequently become infected and efficiently transmit co-evolved viruses. The risk of infection and transmission by competent vectors increases as a function of vector–host contact which may be measured by the vector's reproductive age.

Vectorial Capacity

In general, vector competence defines the ability of a vector to become infected with and transmit an arbovirus, usually under laboratory conditions. By comparison, vectorial capacity (C) is an epidemiological measure of the force of transmission or the daily case dissemination rate, and combines ecological factors relating to the frequency of reservoir host contact (ma, daily vector density in relation to host abundance, squared to account for refeeding), daily vector survival (P), the duration of the extrinsic incubation period (e), and vector competence (V):

$$C = \frac{ma^2 V(P^e)}{-\ln P}$$

Although originally developed to describe the rate of malaria transmission, this formula has been used to describe arbovirus transmission dynamics or to compare the importance of different vector species. For a zoonosis such as WNV, ma^2 becomes bites per bird per night. Frequently, measures of vector abundance (m, originally the man-biting rate) are combined with measures of vector host selection (a, the anthropophagic index or frequency of feeding on humans) to estimate bites per host per day. For zoonoses these terms must be changed to reflect the maintenance host species and the frequency with which they are fed upon by maintenance vector species. Vector blood-meal host-selection patterns determine the vertebrate hosts most frequently infected, and their susceptibility and viremia response then determines the effectiveness of transmission. In general, vectors with a narrow host range that includes susceptible host species will more effectively and rapidly amplify viruses than those with a broad host range that includes both susceptible and nonsusceptible host species. The latter vector species may be important as bridge vectors; for example, *A. aegypti* is a very effective vector of DENV because it feeds almost entirely on humans, whereas *A. albopictus* is less efficient because of its broad host range.

Daily survival (P) typically is measured by examination of host-seeking female reproductive age or from mark–release–recapture studies. In the current formula, P is considered to be constant throughout the life of the vector; however, some studies indicate that mortality rates may actually decrease as a function of vector age, thereby increasing vectorial capacity. The extrinsic incubation period (e) is discussed in detail below, but essentially is the time from infection to transmission by the vector. Vector competence (V) is the same as defined above and measures the ability of the vector to become infected and transmit virus.

Extrinsic Incubation Period

Early in arthropod-transmitted viral epidemics, there are distinct time periods between episodes of new cases that delineate the 'extrinsic incubation period' or virus development outside of the vertebrate or human host. In reality,

this measure of transmission dynamics is related to the time from virus acquisition by the vector until the transmission leads to new cases. Because arthropod body temperature approximates ambient conditions and because virus replication is both temperature limited and dependent, the duration of the extrinsic incubation period changes with latitude and as a function of climate variation, being shortest during summer. Degree–day models can be generated in the laboratory by incubating infected females at different temperatures and measuring the time until they are capable of transmission. Transmission is temperature limited, because viruses have threshold below which they will not replicate. This lower threshold delineates viral distribution in time and space. Theoretically, viruses with a lower (i.e., cool) temperature threshold are expected to have a wider geographic distribution and can be transmitted more effectively at northern latitudes than those with a higher (warm) threshold. Above this lower limit, the rate of viral replication within the vector is dependent upon the temperature of the vector environment and typically increases as an exponential function of ambient temperature. Vector behavior may modify the temperature environment in comparison with ambient conditions, especially during cool periods of the year or day. Species that rest in houses, for example, have a more ameliorated temperature than those that rest outdoors. Nocturnal species that rest in burrows during the day and come out to seek blood-meal hosts at night always enter a warmer environment and therefore their body temperatures may slightly exceed ambient conditions. Both examples of insect behavioral change of body temperature can alter virus replication, transmission rates, and therefore virus amplification.

Phases of Transmission

Transmission dynamics vary over time and space and may be grouped into three phases: introduction or maintenance, amplification or epidemic, and subidence.

Maintenance

Seasonal changes in vector abundance or the autumnal cessation of blood-feeding behavior limit or interrupt arbovirus maintenance transmission. In general, viruses either persist within host populations or become regionally extinct and require reintroduction. At southern latitudes with sufficient vector abundance and warm temperatures, viruses may be transmitted continually during winter. In southern areas with alternating dry and wet seasons, vector abundance changes related to precipitation also dictate the extent and timing of the transmission season. At northern latitudes mechanisms for local maintenance may include persistent infections within either vector or vertebrate host populations that are acquired during fall and then relapse during the following spring. Alternatively, viruses may become regionally extinct and are reintroduced the following spring. Unfortunately, data supporting most overwintering mechanisms are fairly fragmentary despite years of investigation. Recent studies of the molecular genetics of multiple viral isolations made over time and space show patterns of change indicating mutation or extinction, followed by the introduction and persistence of new genotypes. Often, rather small changes in the viral genome can result in marked changes in virulence that affect fitness and therefore amplification. The changes enhancing virulence may be associated with increased host and geographical range. WNV is an example of a virus that has changed genetically, extended its distribution markedly, and has caused serious epidemics throughout northern latitudes in Europe and North America.

Amplification

After maintenance or introduction at low levels, arboviruses undergo seasonal amplification (or increase in the numbers of infected hosts) during favorable weather periods. The rate of amplification is dependent upon vector competence and vectorial capacity factors, but may be limited by vertebrate host immunity and climate. Acquired immunity or depopulation of the primary vertebrate host population during the previous season or seasons may affect transmission during the subsequent season, because a large percentage of infected vectors transmit virus to immune hosts that do not become infective to other vectors. In short-lived vertebrate hosts, such as house sparrows, population turnover rates are high and elevated herd immunity levels short-lived. However, elevated immunity rates in long-lived hosts, such as humans, may limit infection to younger, nonimmune cohorts. A second factor that may constrain transmission is the effect of climate on vector abundance. Arthropod populations tend to vary markedly in response to climate variation. During years when climate is unfavorable, abundance may remain low and below thresholds necessary to effectively amplify virus. During these years maintenance transmission remains at very low levels or virus may disappear during the current and subsequent seasons. In contrast, rapid vector population increases and longer survivorship during favorable weather periods frequently are accompanied by concurrent increases in virus amplification to epidemic levels.

Subsidence

Epizootic and/or epidemic-level transmission may be relatively short-lived and generally is followed by subsidence. Typically, the amplification curve attains asymptotic epidemic levels and then begins to subside due to decreasing numbers of susceptible hosts, seasonal changes

in day length or climate, and/or focused intervention measures. In general, the more intensive and extensive the epidemic transmission, the faster and more widespread the seroconversion or depopulation rates within the primary host population, and the more rapid the focal subsidence. During years with low-level transmission, sufficient naive hosts may remain and provide a source for viral amplification during the following season. Eventually, the numbers of susceptible hosts decrease, slowing the force of transmission and decreasing the numbers of new cases.

Seasonal changes in day length and weather can produce comparable dramatic decreases in epidemic transmission without exhausting the number of available hosts which will remain available for amplification during the following season. At temperate latitudes, the onset of cold weather and shortening photoperiod may induce diapause in the primary vector(s), terminate blood feeding, and interrupt transmission, leading to rapid subsidence. At lower latitudes, comparable seasonality of transmission can be induced by variation in rainfall. Amplification the following season may be dependent upon the intensity of transmission during the end of the previous season and the amount of virus present in the overwintering host populations.

Risk Factors

The risk of infection and disease in vertebrates is related directly to the degree of exposure to host-seeking infectious arthropods and to the vertebrate hosts' immune response to infection.

Residence

Undoubtedly, place of residence markedly affects the risk of infection. Mostly due to the ecology of the arthropod vectors and vertebrate hosts, most arboviruses tend to be focal in their distribution and associated with particular landscapes. Humans often become infected by zoonotic viruses when housing areas are constructed within transmission foci or when human alteration of the landscape creates environments that bring vector and maintenance host together. Rural housing within or adjacent to wooded areas supporting the mosquito *A. triseriatus* has been found to be a critical risk factor for LACV infection in children. In contrast, urban *Culex* populations produced in municipal wastewater systems interfacing with periurban communally roosting American crow populations have led the spatial aggregation of WNV infection risk in humans.

Climate

Climate variation affects temperature and precipitation patterns, mosquito abundance and survival, and therefore arbovirus transmission patterns. These changes often vary at different temporal scales. At temperate latitudes seasonal changes in temperature and photoperiod drive transmission cycles, whereas at tropical latitudes seasonal changes may relate more to wet and dry seasons. The magnitude of annual temperature and precipitation changes may have decadal or shorter cycles based on changes in sea surface temperature, such as the El Niño/southern oscillation change in the Pacific sea surface temperature that markedly alters precipitation and temperature patterns in parts of the Americas. These cycles alter storm tracks that affect mosquito and avian abundance, the intensity and frequency of rainfall events, and groundwater depth.

Age

In the absence of acquired immunity, different viruses seem to exhibit a predilection to cause disease in different host age classes. This may be related to differential biting rates by vector mosquitoes on different host age groups or due to age-related differences in innate immunity. Host-seeking mosquitoes seem to feed more readily on adult than on nestling birds of the same species. With regard to illness, for example, western equine encephalomyelitis virus (WEEV) tends to cause more frequent and severe disease in infants (<1 year), whereas SLEV causes more severe illness in the elderly (>65 years). For endemic viruses, the prevalence of previous infection increases as a function of age, and therefore older cohorts tend to be protected by a greater prevalence of acquired immunity than younger cohorts. This age-related pattern of acquired immunity can change the apparent-to-inapparent ratio of clinical disease for endemic viruses.

Occupation

Different occupations place workers in different environments at different times, and therefore vary their risk for mosquito and arbovirus exposure. For example, farm workers who pick and pack vegetables outdoors at night in southern California were found to have an 11% seroprevalence rate against SLEV, whereas persons residing within Los Angeles were found to have a lower 1.7% exposure rate. In contrast, persons sitting at home in late afternoon in Thailand have a high attack rate by *A. aegypti* and a high exposure rate to dengue viruses, compared to persons working outdoors from morning to night in agricultural professions.

Socioeconomic Status

Historically, socioeconomic status has been related closely to the distribution of cases during urban epidemics. Homes and municipal drainage systems frequently are not well maintained in low-income neighborhoods, and this has shown to be related to the distribution of human cases. In the tropics, lack of a municipal water system and domestic

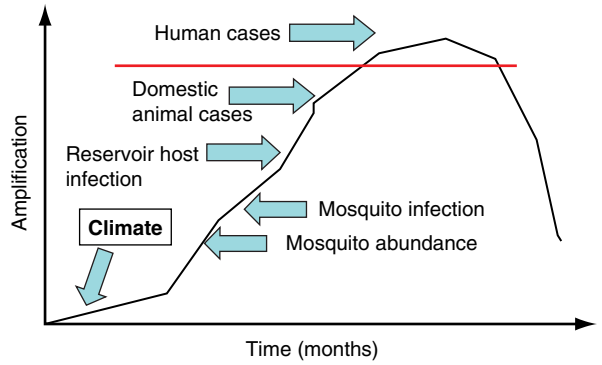

Figure 3 Surveillance indicators used to measure enzootic virus amplification and forecast the risk of human infection. Climate variation can provide the earliest indication of pending risk and may drive the rate of viral amplification.

water storage has been linked strongly to *A. aegypti* abundance and to disease risk.

Forecasting Risk

The cascade of different surveillance measures becoming positive over time as virus amplifies can be used to forecast the risk of human infection, especially for endemic zoonoses. **Figure 3** shows the approximate relative times when surveillance measures might become positive along the enzootic amplification curve for a virus such as WEEV. Usually, human cases are the last factor to be detected and tangential transmission occurs only after considerable WEEV amplification in the mosquito–bird cycle. These surveillance data can be used to focus on mosquito control.

Glossary

Fitness The relative ability of an individual (or population) to survive and reproduce in a given environment.
Helper component (HC)-transcomplementation An HC encoded by a viral genome X mediates the vector transmission of a virus particle containing a viral genome Y.
Horizontal transmission The transmission of a virus, parasite, or other pathogen from one individual to another within the same generation, as opposed to vertical transmission.
Pierce-sucking insects Insects adapted to sap or blood feeding, with the mouthparts transformed into long chitin needles that can pierce and penetrate tissues and allow pumping up their content.
Quasispecies Ensemble of mutant viral genomes constituting a viral population.
Vector Organism acquiring a pathogen on an infected host and inoculating it in a new healthy one.
Vertical transmission The transmission of a pathogen from the parent(s) to the offspring, usually through the germline.

Introduction

Viruses are intracellular parasites diverting the host cellular machinery for their own replication and offspring particles production. As such, they most often negatively affect the hosting cells, sometimes even killing them, and hence repeatedly and unavoidably face the problem of moving on and colonizing new healthy and potent 'territories'. Within a single host, viruses can both diffuse from cell to cell and be transported on longer distances by the vascular system. While animal viruses use membrane

fusions (if enveloped) or membrane receptors to penetrate healthy cells, plant virus entry during the host invasion is always resulting from a passage through 'tunnels' traversing the cell wall, called plasmodesmata, and ensuring a cytoplasm continuity between adjacent cells. Any viral population can grow this way only until the physical limits of the host are reached. Then, a critical passage in the 'outside world' separating two compatible hosts has to be successfully achieved. Because animals are motile and often come in contact, some associated viruses can directly access either blood or permissive tissues of a healthy host and operate a cell entry resembling that involved during invasion of single hosts. However, a most frequently adopted strategy relies on additional organisms, capable of sampling the virus population within an infected host, transporting, disseminating, and efficiently inoculating infectious forms of this virus within host population. Such organisms are designated vectors, giving rise to the term vector transmission. Vector transmission is found frequently in animal viruses and, presumably due to stable hosts and to the need of covering considerable distances between them, has been adopted by the vast majority of plant viruses. Each virus species is submitted to different ecological conditions; hence, an impressive complexity of host–virus–vector interactions has been unraveled over a century of research efforts. The object of this chapter is to synthesize the knowledge available at present in the field of vector transmission of viruses, with a special emphasis on plant viruses, where a great diversity of strategies have been discovered and documented. Indeed, the numerous patterns of vector transmission described for plant viruses include all those reported in animal viruses and many more.

Plant Virus Vectors

Any organism that is creating a break into the cell wall, either for penetrating a plant or simply for feeding on it, and that is capable of covering the distance between two separated plants, can possibly be used as a vector by viruses, for traveling through space and time. Vectors have been described in groups of organisms as diverse as parasitic fungi, nematodes, mites, and most importantly insects (**Table 1**). The pattern of virus uptake, preservation, transport, dissemination, and inoculation can be very

different, due to the specific biology of all three (plant, virus, and vector) partners. However, viruses transmitted by 'pierce-sucking' insects are quantitatively predominant, and the classification established for their various modes of transmission is widely used as a reference for comparison with others. For this reason, hemipteran insect transmission will be described first in details and succinctly compared later on with that by other types of vectors.

Transmission of Plant Viruses by Insects

History of the Classification of the Different Modalities of Transmission

The transmission of plant viruses has been investigated for over a century with the most common vectors being sap-feeding insects with pierce-sucking mouth parts, particularly aphids, and also whiteflies, leafhoppers, planthoppers, and mealybugs. Pioneer studies have demonstrated the complexity and diversity of the interactions between plant viruses and their insect vectors. Even as late as the 1950s, scientists, using the tools at hand, were merely measuring quantitative traits such as the time required for virus acquisition on infected plants and the time during which the virus remained infectious within the vector. Three categories were then defined: (1) the nonpersistent viruses, acquired within seconds and retained only a few minutes by their vectors; (2) the semipersistent viruses, acquired within minutes to hours and retained during several hours; and (3) the persistent viruses that require minutes to hours for acquisition, and can be retained for very long periods, often until the death of the vector. It is important to note that, though the classification and terminology have changed in the last decades, these categories are still used by a number of authors, and thus often encountered in the literature.

In an early study on 'nonpersistent' viruses, the transmission of potato virus Y was abolished by chemical (formaldehyde) or ultraviolet (UV) treatments of the extremity of the stylets of live viruliferous aphids, demonstrating that infectious virus particles were retained there. It was first believed that the transmission of 'nonpersistent' viruses could be assimilated to mechanical transmission, stemming from nonspecific contamination of the stylets, the vector acting simply as a 'flying needle'. Consistent with this was the repeated demonstration that 'nonpersistent' viruses are lost upon moulting of the viruliferous vectors. Later on, the hypothesis of virus uptake during sap ingestion and inoculation during putative regurgitation led to a change from vectors as flying needles to vectors as 'flying syringes', the virus–vector relationship still being considered as nonspecific (**Figure 1**). It is interesting that, while in plant viruses recent data unequivocally convinced the scientific community that the situation is much more complex, likely involving specific receptors in vectors for specific virus species (see the next section), in animal viruses very few studies are available at present and this mode of transmission is still referred to as 'mechanical vector transmission'. The prime conclusion from these experiments is that the virus–vector association occurs externally, on the cuticle lining the food or salivary canal in the insect stylets. Because semipersistent viruses are also lost upon vector moulting, their association with the vector was also proposed to be external, likely in the stylets, though a

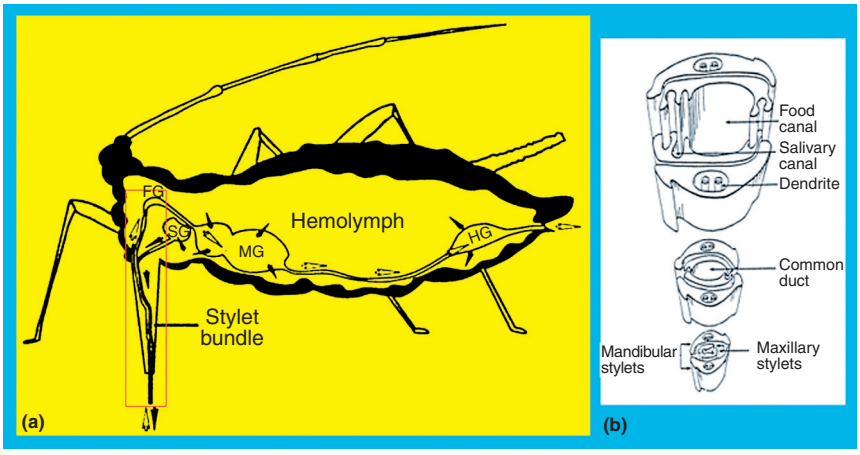

Figure 1 Different routes of plant viruses in their aphid vectors. (a) The white arrows represent the ingestion of circulative viruses, whereas the black arrows materialize their cycle within the aphid body, and inoculation in a new host plant. The red square area indicates the region of the anterior feeding system, where noncirculative viruses are retained in their vectors. (b) Cross sections of the stylet bundle illustrating the inner architecture of maxillary stylets which defines interlocking structures, food canal and salivary canal, fused at the distal extremity into a single common duct, where most noncirculative viruses are thought to be retained (see text). possible location 'upstream', on the cuticle lining the anterior gut of the insect, was also proposed in some cases.

In sharp contrast, many persistent viruses were observed within the vector body by electron microscopy, in various organs and tissues, indicating an internal association with the vectors. Such viruses were shown to pass through the gut epithelium into the hemolymph and join the salivary glands to be ejected together with saliva (**Figure 1**). A latent period of hours to days after acquisition, during which the virus cannot be efficiently inoculated, is consistent with the time needed for completing this cycle within the vector body. Moreover, microinjection of purified persistent viruses within the insect hemolymph subsequently resulted in efficient transmission to new healthy plants, proving that virus within the vector body can get out and be inoculated to host plants.

Altogether, these results prompted a revision of the classification of the modes of transmission in the late 1970s, based on qualitative criteria and still valid today (**Table 2**). The non- and semipersistent viruses were grouped in a new category designated 'noncirculative viruses', and the persistent viruses were named 'circulative viruses'. While circulative animal viruses (arboviruses) in fact infect their vectors where they efficiently replicate, some circulative plant viruses can seemingly operate their cycle in the vector body without any cell infection and replication. Hence, the category 'circulative' has been broken down into the two subcategories: 'propagative' and 'nonpropagative'. The various families and/or genera of plant viruses and their associated vectors and modes of transmission are listed in **Table 1**.

During the last decades, the implementation of molecular and cellular biology has provided invaluable tools for studying the molecular mechanisms of virus–vector interaction. The data currently available for each category are summarized in the following subsections.

Circulative Transmission

Logically, circulative viruses are ingested by vectors, while feeding on infected plants. Some viruses are limited to phloem tissues, which the insect vector can reach within minutes to hours depending on the species, which explains the long feeding period required for their acquisition. As schematized in **Figure 1(a)**, the viruses cross the mid- or hindgut epithelium, are released into the hemolymph, and can then adopt various pathways to traverse the salivary glands, and be released in their lumen, wherefrom they will be inoculated upon salivation into healthy hosts. During this basic cycle , the virus encounters and must overcome diverse cellular barriers, where the existence of specific virus–vector interaction has long been established experimentally, though specific receptors have not been identified so far.

Propagative transmission

Propagative transmission of plant viruses is the homolog of that of arboviruses in vertebrates. Members of the virus families *Rhabdoviridae*, *Reoviridae*, *Bunyaviridae*, and the genus *Marafivirus* are transmitted this way. In compatible virus–vector associations, after infecting the gut epithelium, virus particles are released in the hemocoel cavity and colonize various organs and tissues of the vector, including, ultimately, the salivary glands. The viruses can either diffuse in the hemolymph and concomitantly infect different organs, or follow a constant pattern of spread from organ to organ, as demonstrated for rhabdoviruses which move in (and spread from) the central

Table 2 Different modes of plant virus transmission by insects with pierce-sucking mouth parts

	Circulative		*Noncirculative*	
Transmission modes[a]	*Propagative*	*Nonpropagative*	*Capsid strategy*	*Helper strategy*
Acquisition time[b]	Minutes to hours	Minutes to hours	Seconds to hours	Seconds to hours
Retention time[c]	Days to months	Days to months	Minutes to hours	Minutes to hours
Inoculation time[d]	Minutes to hours	Minutes to hours	Seconds to minutes	Seconds to minutes
Association with vectors[e]	Internal	Internal	External	External
Replication in vectors	Yes	No	No	No
Requirement of an HC[f]	No	No	No	Yes

[a]These modes of transmission were established and are widely accepted for virus transmission by pierce-sucking insects. As discussed in the text, they sometimes also apply to other types of vector.
[b]The length of time required for a vector to efficiently acquire virus particles upon feeding on an infected plant.
[c]The length of time during which the virus remains infectious within its vector, after acquisition.
[d]The length of time required for a vector to efficiently inoculate infectious virus particles to a new healthy plant.
[e]Internal means that the virus enters the inner body of its vector, passing through cellular barriers. External means that the virus binds the cuticle of the vector and never passes through cellular barriers.
[f]A helper component (HC) is involved in cases where the virus particles do not directly recognize vectors, acting as a molecular bridge between the two.

nervous system. Within the vector, all these cases are very similar to genuine infection of an insect host; hence, it is difficult to decide whether insects are proper vectors of propagative viruses, or should rather be considered as alternative hosts. Apart from the genus *Marafivirus*, all propagative viruses are in families that comprise viruses that infect animals, suggesting that they might have evolved from insect viruses by secondarily acquiring the capacity to replicate in plants.

Nonpropagative transmission

This particular association between insect vectors and plant viruses is reasonably well understood only for members of some plant virus species in the family *Luteoviridae*. Such viruses have developed original mechanisms of viral transport, both when passing through gut and salivary gland barriers, and when traveling into the hemocoel cavity.

The cycle of luteoviruses within their vector body involves specific ligand-receptor-like recognition at the cell entry of both the gut epithelium and the salivary glands. While viral ligands are known to be structural proteins of the coat and extension thereof, very little is known about the putative counterpart receptors on the cell membranes of the vectors. Despite this lack of full understanding of the molecular process, many electron microscopy and molecular studies have determined in detail the route of luteovirus particles within the vector, across cellular layers (**Figure 2**). Once the virus reaches either the apical membrane of the gut epithelium, or the basal membrane of the accessory salivary gland cells, and attaches to the specific receptors, it provokes invagination of the plasmalemma, forming small coated virus-containing vesicles. Soon after budding, the coated vesicles deliver the virus particles to a larger uncoated membrane endosomal compartment. Interestingly, luteoviruses mostly escape the route of degradation of internalized material ending in lysosomes. Instead, the virus particles become concentrated in the endosomes, and *de novo* elongated uncoated vesicles are repacked, transporting the viruses to the basal or apical membrane, in gut and accessory salivary gland cells, respectively. The elongated vesicles, which contain rows of virions (**Figure 2**), finally fuse with plasma membranes and release the virus either into the hemocoel cavity or into the lumen of the salivary ducts. Despite these extensive searches of luteovirus particles in their insect vectors, by several independent groups of scientists, no particles have been observed in any organ other than the gut or the accessory salivary glands. Furthermore, classical monitoring of the viral titers within the vector, for assessing viral replication, failed to demonstrate an increase over time. Consequently, it is generally accepted that virus particles, either included in membrane vesicles or suspended in the hemolymph, never come in contact with the cell cytoplasm, thus precluding any possibility of viral replication.

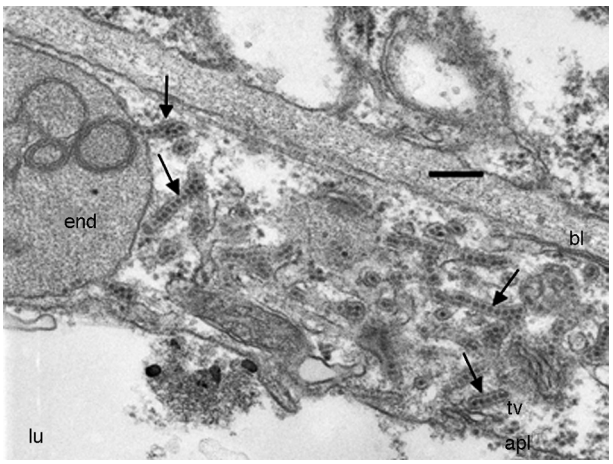

Figure 2 Transcytosis of cucurbit aphid-born yellows virus (family *Luteoviridae*) in hindgut cell of the aphid vector *Myzus persicae*. Luteovirus particles present in the gut lumen (lu) are internalized from the apical plasmalemma (apl) and transported to the basal lamina (bl) in a complex pattern involving different vesicular structures, described in the text. A network of uncoated tubular vesicles is visible (tv indicated by arrows), sometimes connected to the endosome (end). The bar represents 100 nm. The photograph is provided by Catherine Reinbold and Véronique Brault (INRA, Colmar, France). Reproduced from Blanc S (2007) Virus transmission – getting out and in. In: Waigmann E and Heinlein M (eds.) *Viral Transport in Plants*, pp. 1–28. Berlin: Springer, with kind permission of Springer Science and Business Media.

Virus transfer into the hemolymph is believed to occur by passive diffusion. However, the possible impact of the insect immune system at this step of the virus life cycle is often discussed. A study demonstrated that a major protein of the aphid hemolymph, the symbionin, was mandatory for efficient luteovirus transmission. The symbionin is a homolog of the *Escherichia coli* chaperone GroEL, secreted in aphids by endosymbiotic bacteria of the genus *Buchnera*. Eliminating symbiotic bacteria, and thus symbionin, by antibiotic treatments significantly reduced the aphid efficiency as a vector. Consistently, direct evidence of a physical interaction between symbionin and luteovirus particles has been detected in several viral species, and virus mutants deficient in symbionin binding are poorly transmitted. Two hypotheses can explain the positive action of symbionin and are still debated, since no direct proof could be experimentally obtained: (1) it exhibits protective properties, masking the virus to the immune system and maintaining its integrity during transfer through the hostile hemolymph environment, or (2) its putative chaperon activity ensures correct folding facilitating transfer into the salivary glands.

A similar phenomenon was later demonstrated for other circulative nonpropagative viruses (in the family *Geminiviridae*) by other vectors (whiteflies), suggesting

that symbionin participation may be a general phenomenon in this mode of transmission.

Noncirculative Transmission of Plant Viruses

This mode of transmission is by far the most frequently encountered in plant viruses and concerns over 50% of the viral species described to date. Noncirculative viruses do not enter the body of their vectors. They simply attach to receptor sites located externally on the cuticle lining the anterior part of the digestive tract, most often the alimentary/salivary canals within the stylets or the foregut region, and wait until the vector has moved to another plant, where they contrive to be released to initiate a new infection. It has often been proposed that difference between non- and semipersistent viruses, in acquisition and retention time within the vector, was due to a differential location of the binding sites, the former being retained in the stylets and the latter higher up in the foregut. This distinction, however, is not experimentally supported at present, and these two categories should be considered with caution (they are no longer included in **Table 2**). Because noncirculative viruses are adsorbed on the vector cuticle during sap ingestion, and released in many cases during salivation, the favored but still hypothetical location for the retention sites is at the distal extremity of the maxillary stylets, where a single common salivary/food canal is serving for both sap uptake and saliva ejection (**Figure 1(b)**). The best-studied cases of noncirculative transmission are those of viruses in the genera *Cucumovirus*, *Potyvirus*, and *Caulimovirus*, transmitted by various aphid species. Mutagenesis studies of the viral proteins interacting with the vector's mouthparts have clearly indicated that some single-amino-acid substitutions can specifically abolish the virus transmissibility by certain vector species but not by others. Such results, obtained both with cucumber mosaic virus and cauliflower mosaic virus, demonstrate a very specific virus–vector recognition, and strongly suggest the existence of a receptor in the insect mouthparts. Unfortunately, here again and despite the quantitative importance of noncirculative transmission in plant viruses, the viral ligands are well characterized (see below), but the receptors on the insect cuticle stand as the major black box in this field of research, their chemical nature and even their precise location remaining largely hypothetical.

The viral protein motifs directly involved in the attachment to vector putative receptors have been characterized in a number of cases. The frequent occurrence of both transmissible and nontransmissible isolates in the same virus species has greatly facilitated the identification of viral gene regions involved in vector transmission, by simple sequencing of viral genomes, and reverse genetic approaches have been successfully used for definitive confirmation. These investigations clearly revealed two distinct viral strategies for controlling the molecular mechanisms of virus–vector association (**Figure 3**), which represent the currently preferred subcategories in noncirculative transmission (**Table 2**).

The helper strategy

The development of artificial feeding of insect vectors, through stretched parafilm membranes, made it possible to assess the transmission of purified virus particles. The primary striking result was that, in most cases, purified virions are not transmissible, suggesting the requirement of an additional component that is probably eliminated during purification. Sequential feeding on plants infected with transmissible and nontransmissible isolates of such virus species showed that the former produced a compound that could be acquired by the vector, and subsequently mediated the transmission of the nontransmissible isolate. This compound, first described in potyviruses and caulimoviruses, was designated helper component (HC). In both cases, the HC was later purified and demonstrated to be a viral nonstructural protein produced upon plant cell infection, named P2 in caulimoviruses and HC-Pro in potyviruses. P2 and HC-Pro are responsible for specific recognition of the vector. They can be acquired on their own by the aphid and bind to putative receptors within its mouthparts. They exhibit a separated domain, which specifically binds homologous virus particles, thus creating a molecular bridge between virus and vector (**Figure 3**). It is important to realize that HCs can be acquired on their own by the vector, subsequently scavenging virions from homologous species acquired in other locations of the same plant, or even in other plants. This phenomenon extending the assistance between related viral genomes during vector transmission has been termed HC-transcomplementation (**Figure 3**), and may have some important implications in the population genetics and evolution of a virus species (discussed below).

Capsid Strategy

However, for some viruses transmitted by aphids, particularly in the genera *Cucumovirus*, *Alfamovirus*, and *Carlavirus*, purified viral particles are readily acquired and transmitted by the vector. This indicated unequivocally that the coat protein of members of the species must be capable of direct attachment to vector receptors (**Figure 3**). An experiment confirming this conclusion was the demonstration that tobacco mosaic virus, which is not transmitted by any vector, can be transmitted by aphids when its RNA genome is encapsidated *in vitro* into the coat protein of an aphid-transmissible cucumovirus. Recently, the amino acid positions in the coat protein of cucumber mosaic virus, involved in binding to the putative receptors of aphids, have been identified. Their substitution differentially affects the efficiency of transmission by distinct

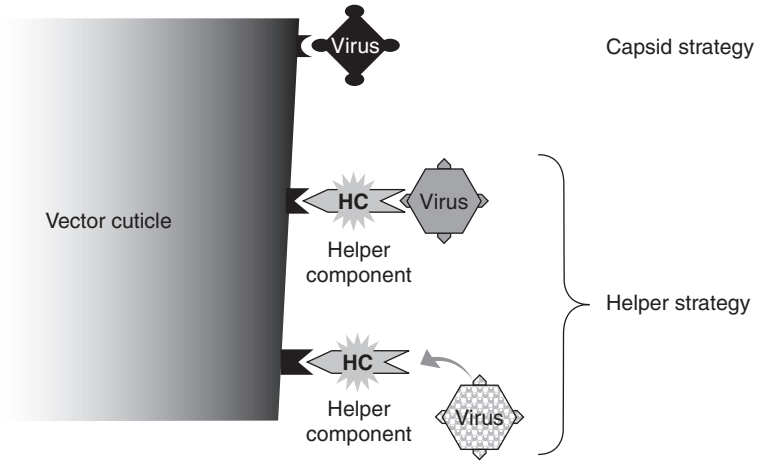

Figure 3 Two molecular strategies for virus–vector interaction in noncirculative transmission of plant viruses. Both strategies allow the retention of virus particles in the vector mouth parts or foregut on putative receptors located at the surface of the cuticular lining. In the capsid strategy, a motif of the coat protein is able to directly bind to the vector's receptor. In the helper strategy, virus–vector binding is mediated by a virus-encoded nonstructural protein (HC), which creates a reversible 'molecular bridge' between the two. HC can be acquired alone, prior to the virion, and thereby allows HC-transcomplementation. In this case, an HC encoded by a genome X (for instance that encapsidated in the gray virion) can subsequently assist in the transmission of a genome Y of the same population, encapsidated in the dotted virion. This possible sequential acquisition of HC and virion is symbolized by the arrow. Reproduced from Froissart R, Michalakis Y, and Blanc S (2002) Helper component-transcomplementation in the vector transmission of plant viruses. *Phytopathology* 92: 576–579, with permission from The American Phytopathological Society.

aphid species, definitely confirming that no HC is required for virus/vector interaction.

Transmission by Beetles

The only cases of insect transmission diverting clearly from one of the patterns detailed above is that described in insect with 'biting-chewing' mouthparts, the best documented examples being beetles, though other insects have a similar feeding behavior.

In contrast to insect with 'pierce-sucking' mouthparts, the beetle feeding is damaging tissues and killing cells, implying an obligate translocation of deposited viruses toward adjacent live cells where they can initiate infection. Beetles have long been reported to acquire and retain viruses from numerous virus species, usually those with highly stable virus particles, and to release them together with the regurgitation of disrupted plant material, lubricating the mouthparts during feeding on new host plants. Surprisingly, however, only some rare species are actually successfully transmitted. A high amount of RNase activity has been found in the beetle regurgitation liquid, and shown to block infection by non-beetle-transmissible viruses. Hence, those viral species that are efficiently transmitted are likely capable of translocation in the vascular system, and/or transfer to unwounded cells, away from the RNase activity. Some virus particles have been detected within the hemolymph of their beetle vector, only seconds after acquisition on infected plants. No correlation between the presence of virions in the hemolymph and success of transmission has yet been established, precluding a possible comparison with the circulative or noncirculative transmission described above.

Transmission by Noninsect Vectors

Although quantitatively less important, noninsect vectors have been identified in several plant virus species. Some are arthropod mites with a morphology distantly related to that of insects, others are totally unrelated organisms such as nematodes or even fungi. However, in many instances, a comparison with the mode of transmission defined in **Table 2** remains possible, demonstrating that this classification can be used as a general basis applicable to all cases of vector transmission.

Transmission by Mites

The transmission of plant viruses by mites has been far less studied, and the molecular and cellular mechanisms of virus–vector relationships remain poorly understood. Several different viral species have been studied and the results suggest the existence of different types of interactions with their respective vectors. This variety is illustrated by two examples: (1) the presence of massive amounts of bromegrass mosaic virus (BMV, family *Bromoviridae*) particles within cells of the gut epithelium of the insect *Eriophyes tulipae* seems to indicate that the virus replicates within the vector, resembling circulative-propagative transmission; (2) wheat streak mosaic virus (WSMV, family *Potyviridae*) appears to be noncirculative. WSMV was

recently demonstrated to interact with its mite vectors through an HC-Pro homolog, thus likely suggesting a helper strategy. Further investigations on additional viral species are required to evaluate the diversity of the modes of transmission found with mite vectors, but it seems likely that they will be closely related to those described for insect vectors in **Table 2**.

Transmission by Nematodes

The transmission by nematode vectors is particularly interesting. Such vectors are moving very slowly in the soil (one or a few meters per year), and cannot disseminate the transmitted virus over long distances. Instead, they retain virus particles, for several months or even years, and usually transmit them in the same location but from plants of a growing season n to plants of the growing season $n + 1$. Consequently, nematode transmission is resulting in a time travel for the virus, rather than a space travel.

Nematodes feed by piercing root cells with protractile stylets, constituting the anterior part of their feeding apparatus, and by ingesting the cell content together with viruses when host plants are infected. In all cases described in the literature, the virus particles are adsorbed on the cuticle lining the foregut and are presumably released from there when inoculated in a new host plant. Since viruses are lost upon moulting of the nematode, the virus–vector association is external and this mode of transmission can be assimilated to the noncirculative transmission. Interestingly, the two subcategories of noncirculative transmission also appear to be represented in nematode transmission. Indeed, among the viruses belonging to two viral genera using nematodes as vectors, *Nepovirus* and *Tobravirus*, viruses in the former genus have been shown to directly attach to the retention sites through their coat protein (capsid strategy), whereas in the latter genus, viruses produce a nonstructural protein which allows transcomplementation (see the helper strategy in **Figure 3**). As in other virus–vector associations, the viral proteins involved in vector recognition were identified, but the putative receptor in the nematodes remains unknown.

Transmission by Fungi

Parasitic fungi are coming in contact with their host plants under the form of motile zoospores, which can digest the root cell wall and penetrate into the cytoplasm, from where they will colonize the whole plant. Two different patterns of virus transmission exist. Some viruses, for instance in the genus *Bymovirus*, are present within the fungus cytoplasm early during formation of the future zoospores in infected plant cells. They will remain inside the zoospore until its cytoplasm is injected in the next host cell. In other cases, for instance in cucumber necrotic virus (genus *Tombusvirus*), the best-studied example of a fungus-transmitted virus, virions are specifically retained at the surface of the zoospore envelope, and inoculated into the plant upon cell wall digestion and fungal penetration. In this case, the receptors of the vector were partially characterized. They have been shown to be distributed at the surface of the zoospore of *Olpidium bornovanus*, and their chemical nature was identified as a glycoprotein.

Altogether, the transmission of plant viruses by fungi can tentatively be regarded as homologous to the categories noncirculative, for those viruses associated to the external coat of the zoospore, and circulative for those internalized in its cytoplasm. Unfortunately, not enough information is available to definitely decide whether viral replication is effective within the fungus, and hence whether both propagative and nonpropagative subcategories are present.

Transmission and Evolution

One aspect of vector transmission that is rarely considered in the literature is its evident impact on the population genetics and evolution of viruses. Indeed, while vector transmission is always regarded as an excellent means of maintenance and spread within host populations, it also implies that the virus is able to solve certain problems. First of all, one must bear in mind that a virus population rapidly accumulates very numerous mutations and develops a swarm of genome variants generally designated 'quasispecies'. In such a genetic context, the virus sample collected, transported, and inoculated by the vector will be highly variable. This sample, which gives rise to a new population after each round of vector transmission, will obviously condition the composition of the viral lineage, and thus its evolution. In this regard, two key parameters must be considered:

1. The distribution of viral variants within the host plant determines what is actually accessible for sampling by the vector. If variants are homogeneously distributed within the whole plant, several can be acquired together by the vector. In contrast, if they are physically isolated in different cells, organs, or tissues, only one or few will be collected.
2. The pattern of the virus acquisition by the vector can dramatically change the composition of the transmitted viral sample. When a given vector collects the virus all at once in a single location, the diversity of genome variants transmitted tends to be restricted. On the other hand, collecting the viral sample bits by bits upon successive probing in different locations of the infected host will increase the genetic diversity of the pool of viral genomes transmitted.

It has been repeatedly demonstrated experimentally that successive genetic bottlenecks imposed in viral lineages are

drastically decreasing the mean fitness of RNA virus populations, sometimes even driving them toward extinction. One can then easily conceive that viruses will develop strategies to avoid or compensate for genetic bottlenecks during their life cycle. It is highly probable that different strategies of vector transmission found in plant viruses have different impacts on the fitness and evolution of viruses, through the different pools of genome variants that are collected and inoculated. For instance, in the helper strategy, it has been suggested that HC-transcomplementation (**Figure 3**) allows the vector to sample viruses in several steps and in several locations of the host, thus opening the genetic bottleneck, and perhaps attenuating its detrimental effect.

Future Prospects

From a mechanistic standpoint, future advances will mainly concern the characterization of the vector receptors that are used by viruses to ensure successful transmission. Indeed, none of these molecules have been identified so far, in any vector species and category of transmission. Apart from the example of the fungus-transmitted CNV described above, not even their chemical nature and precise location have been established.

From an evolutionary standpoint, two aspects have been mostly neglected in spite of their undeniable importance: (1) the size of the virus sample transmitted by a given vector remains largely unknown in most cases, (2) the distribution of the genome variants, constituting the swarm of mutants of the viral quasispecies, within different cells, organs, and tissues of the host plant is largely unresolved, precluding any evaluation of what genetic diversity from a given viral population is actually accessible to the vectors.

Vegetable Viruses

P Caciagli, Istituto di Virologia Vegetale – CNR, Turin, Italy

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Incubation The time period from the initial infection (inoculation) to the manifestation of the disease (symptoms). For virus diseases of vegetables, incubation can vary between 2 and 40 days, most commonly between 1 and 3 weeks.

Meristem A tissue in plants consisting of undifferentiated cells, found in zones of the plant where growth (cell division) can take place (meristematic dome). The term 'meristem tip' is used to denote the meristem dome together with 1–2 primordial leaves and measuring between 0.1 and 0.5 cm in height.

Roguing The practice of removing diseased (or abnormal) plants from a crop.

Vector An organism capable of transmitting a pathogen from one plant host to another by establishing specific relationships with the pathogen itself.

Vegetables

The plant species/subspecies cultivated as vegetables are close to 200 and belong to more than 30 botanical families, representing, with fruits, about 35% of the total

food derived from plants (including cereals, vegetable oils, and sugar crops).

Viruses

According to different estimates, 3–5% of overall vegetable production is lost to virus infections, but losses can be occasionally very high, and are normally higher where pest control is lower, for example, in developing countries.

Keeping in mind that viruses of potato, sweet potato, cassava, and legumes are not considered in this article, as they are dealt with elsewhere in this encyclopedia, a total of about 200 viruses (excluding cryptic viruses, satellites, and viroids) have been reported as naturally infecting 67 of the 129 vegetables considered here. These viruses belong to 30 genera in 15 families and to nine genera unassigned to families; eight viruses are in three families, but have not been assigned to genera, and three more viruses have not been assigned to any taxa (**Table 1**).

Table 1 Taxonomic assignment of vegetable viruses, their numbers per genus, and their vectors

Genome type	*Family*	*Genus*	*No. of virus species*	*Vectors*
Single-stranded DNA	*Geminiviridae*	*Begomovirus*	35	Whiteflies
		Curtovirus	2	Leafhoppers
		Mastrevirus	1	Leafhoppers

		Umbravirus	3	Aphids
	Unassigned family	Unassigned genus	1	Plasmodiophorids
			2	Not known

As tomatoes, watermelons, cabbages, onions, cucumbers, and eggplants make up almost 50% of the total vegetable production (legumes, potatoes, sweet potatoes, and cassava excluded), it is no wonder that more than 90 viruses have been found in these crops, with about 50 viruses in tomatoes, the most cultivated vegetable of all (about 13% of the total) (**Table 2**).

Ecology and Epidemiology

Factors normally considered in epidemiological studies are hosts, pathogens, and environment. To these, we can add vectors and human action.

Host

Among possible reactions of a plant to virus attack, only susceptibility and tolerance (plant systemically infected with very mild or no visible effects) favor the spread of viruses. It is evident, from both the number of viruses isolated and the number of vegetables found naturally infected, that most vegetables escape virus infections, for a number of different reasons, including resistance, possibly as a consequence of centuries of human selection for good-looking products. In fact, only 38 vegetables are infected, under natural conditions, by more than one virus, and only 25 by more than two viruses.

Table 2 The top vegetables in the world (excluding potato, sweet potato, cassava, and legumes), their production, and the number of viruses found in each crop in natural infection

Vegetable	*Family*	*Production*[a]	*Viruses*[b]
Tomato	Solanaceae	126.1	53
Watermelon	Cucurbitaceae	97.1	14
Cabbages	Brassicaceae	66.7	2
Onion	Alliaceae	62.1	4
Yam	Dioscoreaceae	46.7	3
Cucumber	Cucurbitaceae	41.6	20
Plantain banana	Musaceae	33.0	2
Eggplant	Solanaceae	30.4	8
Pepper	Solanaceae	27.2	28
Carrot (and turnip)	Apiaceae	23.8	13
Lettuce and chicory	Asteraceae	21.9	21
Squash, pumpkin	Cucurbitaceae	20.4	3
Cauliflower and broccoli	Brassicaceae	17.7	3
Garlic	Alliaceae	14.2	9
Spinach	Chenopodiaceae	12.8	10
Taro	Araceae	11.3	3
Asparagus	Asparagaceae	6.6	6
Okra	Malvaceae	5.3	2
Leek	Alliaceae	1.8	3
Artichoke	Asteraceae	1.4	14
Total		881	193[c]

[a]Data, expressed in millions of tons, refer to year 2004; from data made available by the Food and Agriculture Organization, United Nations.
[b]Number of viruses detected from natural infections; the same virus may infect more than one vegetable.
[c]Total of different virus species detected in vegetables.

Pathogen

The main virus features that affect epidemiology are variability, host range, and transmission pathways. The higher the variability of a virus, the higher is its chance to adapt to new hosts and environments. Most vegetable viruses (as most plant viruses) have a single-stranded RNA (ssRNA) genome, the genome most prone to errors during replication, as it lacks the proofreading mechanisms that are present in DNA replication. Although it has some drawbacks, this feature ensures a high level of variability to viruses with a single genome component. Viruses with a divided genome can also count on natural reassortment of multiple-component genomes to increase their variability. This can strongly influence the host range of the virus. Out of 76 viruses infecting more than one vegetable crop, only 12 naturally infect more than five crops, with eight of them having an ssRNA divided genome (viz., alfalfa mosaic virus, arabis mosaic virus, cucumber mosaic virus, lettuce infectious yellows virus, radish mosaic virus, squash mosaic virus, tobacco rattle virus, and tomato black ring virus); six of these have vegetable hosts in more than one botanic family. Viruses of vegetables with a divided genome are only 30% of the total. The analysis of the host-range done for this work does not include all cultivated plants and, furthermore, the host range of viruses is not usually restricted to cultivated plants, but nevertheless the number of crops naturally infected is a good indicator of the host-range width. The host range is also strictly interconnected to the ways viruses are transmitted. Viruses, even those infecting centenary trees, need to be able to pass from one susceptible host to another. The means by which viruses move from host to host can be summarized as (1) vectors (flagellate protists: plasmodiophorids, fungi, nematodes, and arthropods); (2) seed and pollen; (3) vegetative propagation; and (4) mechanical transmission.

1. Vectors of the viruses infecting vegetables are shown in **Table 1** (column 5). Transmission by vectors involves all epidemiological factors: the virus, the vector, the host plant, the environment, in both the biotic and abiotic aspects, and man-action, in the form of movement of vectors, viruses, and host plants around the world.
2. Out of the 134 viruses that infect vegetables and have been studied for seed transmission, only 33 are seed transmitted in some plants. However, only 15 (listed

in **Table 3**) are seed-transmitted in vegetables. Nevertheless, seed transmission is of paramount importance, as it can start virus infection in a newly planted crop. All viruses known to be seed-transmitted in vegetables have single-stranded, positive-sense RNA genome.

3. Viruses that are vegetatively propagated are listed in **Table 4** together with the number of viruses reported from natural infection in each crop. With the exception of artichoke, the number of virus detected is linked to the distribution of crops in terms of both the total production and cultivation areas outside the center of origin.

4. Mechanical transmission is particularly important for viruses (for instance, tobamo- and potexviruses) that reach high concentration in their vegetable hosts, particularly in the epidermis and hairs, and maintain infectivity for a long time in the environment. The risk is particularly high for crops frequently manipulated during the growing season, as man and his tools can act as carriers. Mechanical transmission due to repeated cuts for harvesting are known for zucchini yellow mosaic virus in zucchini squash, and for radish mosaic virus in rocket (eruca).

The case of tobacco mosaic virus (TMV) is worth a special mention, as an example of a 'seed-mechanical' transmission: TMV can contaminate the tegument of a tomato seed and from here infect the seedling during its growth. A special case is also the pollen-mediated transmission of tobacco streak virus and pelargonium zonate spot virus. These viruses can be mechanically inoculated by thrips that rub contaminated pollen on the leaf surface while moving on a host plant.

Environment

The environment has an influence on virus spread through both biotic and abiotic factors. Among biotic factors, the most important is wild vegetation that can act as reservoir for viruses, and fauna that may include potential vectors. Among abiotic factors, soil has an influence on vectors of soil-borne viruses. Light, sandy soils favor the spread of nematode-borne viruses, while heavy, water-retaining soils favor the spread of plasmodiophorid- and fungal-borne viruses. Rain and humidity, wind, and, most of all, temperature has a strong influence on virus epidemiology, because of their effects on arthropod vectors. High humidity and moderate temperatures favor multiplication of aphids, while strong winds and rains impair their long-distance movements. Higher temperatures are more suited for whiteflies and leafhoppers. So, it is not by chance that whitefly-borne viruses are more common in areas with subtropical climate, and

Table 3 Viruses transmitted through vegetable seeds

Family	*Virus (genus)*	*Vegetable*	*Species*	*Family*
Comoviridae	Squash mosaic virus (*Comovirus*)	Watermelon	*Citrullus lanatus (C. vulgaris)*	Cucurbitaceae
		Squash, pumpkin	*Cucurbita maxima*	Cucurbitaceae
	Chicory yellow mottle virus (*Nepovirus*)	Parsley	*Petroselinum crispum* subsp. *tuberosum*	Apiaceae
		Chicory	*Cichorium intybus*	Asteraceae
	Beet ringspotvirus (*Nepovirus*)	Mangolds (beet roots, fodder beet)	*Beta vulgaris*	Chenopodiaceae
		Swiss chard	*Beta vulgaris* var. *cicla*	Chenopodiaceae
	Tobacco ringspot virus (*Nepovirus*)	Lettuce	*Lactuca sativa*	Asteraceae
	Tomato black ring virus (*Nepovirus*)	Celery	*Apium graveolens*	Apiaceae
		Lettuce	*Lactuca sativa*	Asteraceae
		Tomato	*Solanum lycopersicon*	Solanaceae
Potyviridae	Celery latent virus (*Potyvirus?*)	Celery	*Apium graveolens*	Apiaceae
	Lettuce mosaic virus (*Potyvirus*)	Lettuce	*Lactuca sativa*	Asteraceae
Tombusviridae	Tomato bushy stunt virus (*Tombusvirus*)	Pepper	*Capsicum annuum*	Solanaceae
		Tomato	*Solanum lycopersicon*	Solanaceae
	Cucumber leaf spot virus (*Aureusvirus*)	Cucumber	*Cucumis sativus*	Cucurbitaceae
Bromoviridae	Alfalfa mosaicvirus (*Alfamovirus*)	Pepper	*Capsicum annuum*	Solanaceae
	Spinach latent virus (*Ilarvirus*)	Spinach	*Spinacia oleracea*	Chenopodiaceae
Unassigned to family	Cucumber green mottle mosaic virus (*Tobamovirus*)	Squash, pumpkin	*Cucurbita maxima*	Cucurbitaceae
		Watermelon	*Citrullus lanatus (C. vulgaris)*	Cucurbitaceae
	Pepper mild mottle virus[a] (*Tobamovirus*)	Pepper	*Capsicum annuum*	Solanaceae
	Tobacco mosaic virus[a] (*Tobamovirus*)	Pepper	*Capsicum annuum*	Solanaceae
		Tomato	*Solanum lycopersicon*	Solanaceae
	Tomato mosaic virus[a] (*Tobamovirus*)	Tomato	*Solanum lycopersicon*	Solanaceae

[a]Transmission of tobamoviruses is not a true seed transmission as a result of embryo infection, but a 'seed-mechanical' transmission; TMV can contaminate the tegument of a seed and from here infect the seedling during its growth.

Table 4 Vegetatively propagated vegetables from which viruses have been reported, and the number of viruses reported in natural infections

Species	*Common name*	*Family*	*No. of viruses reported*
Cynara scolimus	Artichoke	Asteraceae	14
Allium sativum	Garlic	Alliaceae	9
Asparagus officinalis	Asparagus	Asparagaceae	6
Allium ascalonicum	Shallot	Alliaceae	5
Colocasia esculenta or *C. antiquorum*	Taro	Araceae	4
Ullucus tuberosus	Olluco	Basellaceae	4
Canna edulis	Achira	Cannaceae	3
Dioscorea spp.	Yam	Dioscoreaceae	3
Arracacia xanthorrhiza	Arracacha	Apiaceae	2
Musa spp.	Plantain banana	Musaceae	2
Tropaeolum tuberosum	Mashua	Tropaeolaceae	2
Rorippa (Nasturtium) officinale or *R. officinale* × *R. microphyllum*	Water cress	Brassicaceae	1
Bambuseae (tribe)	Bamboo shoot	Poaceae	1

that the global warming is accompanied by an increase of their importance and diffusion areas.

Control Measures

Control of virus and virus diseases in vegetables, as in most crops, is indirect and based upon a number of strategies for preventing virus infection. Seeds should be as virus-free as possible, using certified seeds whenever possible, disinfecting seeds of crops susceptible to tobamoviruses by a number of simple, but effective chemical treatments, when certified seed is not available. Multiplication material of vegetatively propagated species (**Table 4**) need to be selected and virus-free vegetative stock prepared and maintained. For freeing plant material from viruses one can use (1) heating of dormant plant parts (thermotherapy) and growing small shoot tips removed immediately after heat treatment; (2) meristem tip culture, particularly efficient for eliminating viruses from plants of the family Araceae, for example, may be preceded by or associated with heat treatment (very effective for garlic, for example); (3) chemical treatment with antiviral substances, like ribavirin, either alone or with DHT; usually disappointing, it may work in association with the other two methods. Seedlings should be protected before and soon after transplanting as plants are usually very susceptible at this stage. After transplanting, it is important to prevent virus spread from outside and within the crop. Contamination from the soil can be avoided by removing debris from previous crop (particularly for tobamo-, tombus-, and carmoviruses) or by crop rotation, alternating crops susceptible to different viruses; crop rotation may help also in controlling vectors of limited mobility (nematodes, fungi, plasmodiophorids). Crops can be protected against airborne vectors by physical means, either excluding the vectors (nets and covers of various types, wind-breakers) or repelling them (mulching with repellent effect, e.g., UV-reflective silver plastic), or by chemical treatments. Biologic control of vectors is not very efficient, particularly against introduction of viruses into the crop, as efficient vectors can be occasional visitors of the crop rather than regular colonizers. Control of weeds and volunteer plants from the previous crop is also very important in reducing early infections. When a vegetable is grown on a wide territory crop after crop, a 'crop-free period' can be very efficient in preventing virus infections (e.g., carrot virus Y in carrots in southern Australia). As for avoiding the introduction of viruses in areas (islands, countries, continents) where they are not present yet, most agriculturally advanced countries set quarantine rules aimed at excluding specific viruses (or their vectors) or limiting their further spread; setting and applying quarantine measures can be quite complex, but it may be worth particularly for viruses transmitted through seed or in dormant vegetative parts. In order to control the spread of viruses within the crops, one needs to reduce the movement of viruses. For vector-borne viruses, a number of chemical treatments are available for controlling the different vectors. Hygiene of operator and implements (by washing with a solution of 3% trisodium orthophosphate, for example) is particularly important for viruses readily mechanically transmissible (tobamo-, potex-, carmoviruses, but also comoviruses) in crops that need frequent tending. Roguing can be effective only if virus incidence is still low (e.g., less than 10%), the incubation is short, and the movement of the virus from plant to plant, by whatever means, is slow. When roguing plants hosting vectors, care should be taken not to disperse them while removing plants. A further possibility for protecting a vegetable crop from virus damage is artificial infection of the plants with a strain of the virus causing only mild disease symptoms (cross-protection) or associating a satellite to a virus to the same aim (e.g., cross-protection is used for protecting cucurbits from damages caused by zucchini yellow mosaic virus and tomatoes from tomato mosaic virus; co-infection with a satellite can be used to reduce damages by cucumber mosaic virus in pepper and tomato). Both methods have a number of objections, based on ecological and practical considerations, so they are not recommended as general practice, but still can reduce virus

damages at least for some time in some crops. Another method of choice to avoid virus infection of vegetables is resistance, to vectors in few instances (aphids, whiteflies, thrips) and to viruses in many cases. For analysis of resistance to viruses, either natural or engineered, readers are referred to specific articles of this encyclopedia. **Table 5** lists some of the crops, and their viruses, for which natural resistance is commercially available. Transgenic lines of vegetables have been developed that resist to very damaging viruses, but they are not listed here because, for a number of reasons, transgenic seeds are not available to the majority of growers yet.

A Few Special Cases

A few viruses infecting vegetables and the symptoms they cause in their hosts are hereafter described, chosen as examples among the many vegetable virus diseases. For details on the structure and properties of the viruses mentioned, the reader is referred to the specific articles of this encyclopedia.

Cucumber Mosaic Virus

Cucumber mosaic virus (CMV) is a positive-sense ssRNA virus with a tripartite genome encapsidated in isometric particles measuring about 30 nm in diameter. CMV has a very wide host range (more than 800 species in 70 botanic families). Natural infections have been reported from at least 10 vegetable species and in a large number of weeds, the most important virus reservoir. In many of these weeds CMV is not associated to any symptoms and is efficiently seed-transmitted. The virus is transmitted by several aphid species in a nonpersistent manner: infectivity is retained by vectors for a few hours and is lost with molt. Symptoms of CMV in vegetables like tomato plants infected at an early stage are chlorotic local lesions between the secondary leaf vein. Necrosis, first in the form of brown leaf areas, and later as brown lines along petioles and stems, proceeds toward the bottom of the plant, which can die in a few weeks after infection. Fruits, if present, are misshaped, sun-burnt, and necrotic. Plants infected at a mature stage normally show growth reduction, bushy appearance, and leaf deformation (shoestring-like leaves). Fruits have reduced size and do not ripen. Depending on a number of factors, including the presence of satellite RNAs, plants may have normal-looking leaves but show necrosis of fruits (losses are quite reduced in this case) or show typical, but stronger symptoms (in this case, losses can be very high). Symptoms of CMV infection in 'pepper' plants depend on the virus strain and on the plant age at the moment of infection. In young pepper plants CMV causes leaf yellowing and narrowing, and necrotic symptoms, on both the foliage and the fruit. If older plants are infected, CMV symptoms can be mild and appear on lower, yellowing leaves as green ring spots or oak-leaf patterns, but also as a mild mosaic, with a general dull appearance. Cucurbits infected by CMV, particularly zucchini, squash, and melons, show strong mosaic

Table 5 Vegetables and viruses for which natural resistance of different degrees has been incorporated in commercially available cultivars

Species	*Common names*	*No. of viruses reported*	*Genetic (natural) resistance available to*
Lactuca sativa	Lettuce	20	Lettuce mosaic virus (*Potyvirus*)
Brassica oleracea var. *capitata*	Cabbage	2	Turnip mosaic virus (*Potyvirus*)
Spinacia oleracea	Spinach	10	Cucumber mosaic virus (*Cucumovirus*)
Cucumis sativus	Cucumber	20	Cucumber mosaic virus (*Cucumovirus*), papaya ringspot virus (*Potyvirus*), watermelon mosaic virus (*Potyvirus*), zucchini yellow mosaic virus (*Potyvirus*)
Cucurbita maxima	Squash, pumpkin	3	Cucumber mosaic virus (*Cucumovirus*), papaya ringspot virus (*Potyvirus*), watermelon mosaic virus (*Potyvirus*), zucchini yellow mosaic virus (*Potyvirus*)
Cucurbita pepo	Zucchini, marrows, pumpkin, squash	14	Cucumber mosaic virus (*Cucumovirus*), papaya ringspot virus (*Potyvirus*), watermelon mosaic virus (*Potyvirus*), zucchini yellow mosaic virus (*Potyvirus*)
Capsicum annuum	Pepper	27	Cucumber mosaic virus (*Cucumovirus*), pepper mottle virus (*Potyvirus*), potato virus Y (*Potyvirus*), tobacco etch virus (*Potyvirus*), tobacco mild green mosaic virus (*Tobamovirus*), tobacco mosaic virus (*Tobamovirus*), tomato spotted wilt virus (*Tospovirus*)
Solanum lycopersicon	Tomato	53	Tobacco mosaic virus (*Tobamovirus*), tomato mosaic virus (*Tobamovirus*), tomato spotted wilt virus (*Tospovirus*)
Solanum melongena	Eggplant (aubergine)	8	Cucumber mosaic virus (*Cucumovirus*), tomato mosaic virus (*Tobamovirus*)

symptoms and leaf narrowing, and distortion (**Figure 1**). Fruits are pitted and misshapen, unmarketable. To worsen things, mixed infections with other viruses are common. Celery and parsley infected by CMV show leaf yellowing and necrosis. 'Lettuce' infected by CMV shows intense mosaic, vein chlorosis and, frequently, vein browning and necrosis when temperature drops below 13 °C. CMV infection of spinach causes a variety of symptoms including stunting, yellowing, and mottling of the older leaves and malformation of the younger leaves.

Garlic Viruses

Because of exclusive vegetative propagation, by cloves or, in some cultivars, by inflorescence bulbils, garlic is particularly prone to accumulate complex virus infections. The most known virus-associated syndrome in garlic is mosaic. Symptoms include various degrees of leaf discolorations, most pronounced in the younger leaves, chlorotic mottling, striping, and streaking. Plants are also stunted compared to healthy looking plants under the same conditions. Most probably, two potyviruses are responsible for mosaic in garlic: one is a garlic strain of onion yellow dwarf virus (OYDV-G), the other a specific strain of leek yellow stripe virus (LYSV-G). Garlic clones, first freed from OYDV and LYSV and then mechanically inoculated with either virus, have been shown to suffer yield reduction from 17% to 60% depending on the virus–cultivar combinations. Yield losses are worse in case of mixed infections or chronic infections (vegetatively propagated material originally infected). Two aphid-borne carlaviruses, garlic common latent virus (GarCLV) and shallot latent virus (SLV), also known as garlic latent virus (GarLV), have also been identified as parts of the garlic virus complex. A number of allexiviruses (genus *Allexivirus*; family *Flexiviridae*) have been identified in recent years in garlic. Although none of them has been associated with any particular symptom, some of them cause yield effects, particularly in mixed infections with OYDV and LYSV. Garlic dwarf virus (GDV) (family *Reoviridae*; genus *Fijivirus*), originally isolated in France, causes well-defined symptoms of dwarfing and leaf thickening.

Tobamoviruses

Tobamoviruses are possibly the most-studied viruses of plants. Tobamoviruses have rod-shaped particles 300 × 18 nm, each containing a single molecule of positive-sense, ssRNA. Particles are very stable. No biological vector is known, but because of high stability and high concentration in plant tissues, tobamoviruses are readily transmitted mechanically during crop tending. They are also seed-transmitted but, as mentioned before, in a manner very different from true seed transmission. Tobacco mosaic virus (TMV) (from which the name of the genus is derived) and tomato mosaic virus (ToMV) are the most known, but other viruses, pepper mild mottle virus (PMMoV) and tobacco mild green mosaic virus (TMGMV), infect vegetables in the family Solanaceae and can be differentiated by biological and serological tests. TMV, ToMV, and PMMoV commonly infect peppers, causing chlorotic mosaic, leaf distortion, sometimes systemic necrosis, and defoliation, depending on the usual factors: plant cultivar and age, virus strain, light intensity, and temperature. Fruits are disfigured, with discolored or necrotic areas. PMMoV usually causes milder symptoms on leaves but is more severe on fruits. TMGMV has been found occasionally in pepper. Tomato plants are mostly infected by ToMV, but occasionally also by TMV. The most characteristic symptoms are mottled areas of light and dark green on the leaves. Plants infected at an early stage of growth are yellowish and stunted. Leaves may also be malformed, narrowed, although not as much as with CMV, or showing enations (outgrowths) on the lower leaf lamina. High temperature can mask leaf symptoms. Fruits can be from almost normal to misshapen and be reduced in size and number, showing uneven ripening, corky or necrotic rings, internal browning. TMV and ToMV can infect eggplant occasionally, causing mild symptoms on both leaves and fruits.

Tomato Spotted Wilt Virus

Tomato spotted wilt virus (TSWV) is the type member of the genus *Tospovirus* in the family *Bunyaviridae*. Virus particles are roughly isometric, 80–90 nm in diameter, enveloped in a lipoprotein membrane, contain three single-stranded linear RNAs, one of negative and two of ambisense polarity, associated with a nucleoprotein to form the nucleocapsid. TSWV is transmitted by thrips in a circulative, propagative manner. It can infect hundreds of species in 70 botanical families. The first symptoms of TSWV infection in tomato are chlorotic

spots, 3–4 mm in diameter, on apical leaves, rapidly turning to bronze and dark-brown (necrosis). If infected when young, the plant will eventually die. If infected later, dark brown streaks also appear on stems and leaf petioles; growing tips are greatly stunted, and usually severely affected with systemic necrosis. Fruits, mostly reduced in size, will display characteristic symptoms – immature fruit have mottled, light green rings with raised centers that develop to orange and red discoloration patterns on mature fruits (**Figure 2**). TSWV-infected pepper shows symptoms similar to those described for tomatoes. Plants infected at a very early stage are usually severely stunted and yield no fruit. Plants infected later show chlorotic or necrotic rings on leaves and stems. Some cultivars react with flower and leaf drop. Fruits develop necrotic or discolored spots or rings. Lettuce and endive infected when young turn yellow, collapse, and die. Older plants develop marginal wilting, yellowing, and necrosis of the leaves. Typical is the bending of midribs as a consequence of symptoms appearing only on one half of the leaf. The plant may also look twisted. Endive appears to be more susceptible than lettuce. Chicory infected by TSWV has a stunted, bushy, yellowish look, with chlorotic necrotic spots along the midribs and secondary veins. Eggplants and artichokes can also be naturally infected by TSWV, but only occasionally.

Turnip Mosaic Virus

Turnip mosaic virus (TuMV) is a typical member of the genus *Potyvirus* in the family *Potyviridae*. It has nonenveloped, filamentous virions, usually flexuous, with a modal length of 720 nm, containing a monopartite, positive-sense ssRNA genome. It is transmitted by several species of aphids in a nonpersistent manner. It has a relatively wide host range; naturally, infections occur mainly in the family Brassicaceae and in few weeds outside this family. All *Brassica* species are susceptible to TuMV. The virus also infects lettuce, watercress, radish, and rocket, and it is present all over the world. Young leaves of infected cauliflower plants show chlorotic ringspots followed, as the leaf ages, by yellow or brownish spots surrounded by circular or irregular necrotic rings. Generally, these occur in the vicinity of the leaf veins. Leaf blight appears in infected sections when many lesions coalesce. Outer leaves of infected cabbages may show ringspot pattern or appear more uniformly necrotic, but, as the leaves age, a chlorotic color almost replaces the normal green tissue. In white cabbage, the occurrence of internal necrotic lesions, sunken and coalescent, has been correlated with the presence of field symptoms of turnip mosaic virus. This postharvest disorder may result in the loss of large quantities of stored cabbage. Symptom expression is temperature sensitive, with most pronounced symptoms at temperatures ranging from 22 to 30 °C, and is very much masked below 17 °C. Other *Brassica* species, like turnip, broccoli, and Chinese cabbage, react to TuMV infection with different degrees of mosaic, necrosis, leaf distortion, and reduced growth.

Figure 2 Symptoms of tomato spotted wilt virus infection on tomato fruits. Courtesy of the late P. Roggero.

Tomato Yellow Leaf Curl Virus and Related Begomoviruses

Tomato yellow leaf curl virus (TYLCV) is a member of the genus *Begomovirus* in the family *Geminiviridae*. It has geminate particles measuring 20 × 30 nm and encapsidating a monopartite genome of circular, ssDNA 2.8 kbp in size. The virus is transmitted by the whitefly *Bemisia tabaci* in a circulative manner, but it is not mechanically transmissible. Seed transmission has not been reported. TYLCV has a relatively narrow natural host range. Infected tomato plants are stunted, with branches and petioles tending to assume an erect position. Leaflets of the infected plants are smaller than those of healthy ones and upward curled with margins more or less yellow (**Figure 3**). Flowers have a normal appearance, but fruit production is strongly reduced. TYLCV was first described in Israel and it is now known to be present in the Mediterranean basin, in Egypt and Sudan, in Iran, and in the Caribbean basin. A number of monopartite begomoviruses, transmitted by *B. tabaci*, inducing very similar symptoms on tomato plants, with some differences in the host range and significant differences in their sequences, have been described in recent years and classified as distinct species of the genus *Begomovirus* (e.g., *Tomato yellow leaf curl Sardinia virus*). Similar symptoms on tomato plants are induced by other begomoviruses, named in the same way, but are actually bipartite viruses (e.g., tomato yellow leaf curl China, -Iran, -Thailand virus); some of these viruses may be mechanically transmissible with difficulties. A few other begomoviruses, named tomato leaf curl someplace virus, where someplace is the name of the area (state, country) of origin, may induce some yellowing of tomato leaves, despite the name. Molecular diagnostics are therefore the only tools for identification of begomoviruses inducing yellow leaf curl symptoms in tomato plants.

Figure 3 Leaves of a tomato plant infected by tomato yellow leaf curl virus (right) compared to leaves of a healthy plant (left).

Figure 4 Symptoms of zucchini yellow mosaic virus infection on zucchini fruits. Courtesy of the late P. Roggero.

Zucchini Yellow Mosaic Virus

Zucchini yellow mosaic virus (ZYMV) is a typical member of the genus *Potyvirus* (family *Potyviridae*) (see TuMV). It is transmitted by several species of aphids in a nonpersistent manner and its natural host range is essentially limited to members of the family Cucurbitaceae. ZYMV is a 'recent' virus – it was first detected in 1973 in southern Europe, the first epidemics were reported in 1979–80, and in 1996 it was already present practically in all the areas where cucurbits are grown. We still lack an acceptable explanation for the rapid worldwide diffusion of the virus. Early symptoms in infected zucchini appear as vein clearing of fine leaf veins, followed by a general yellowing of the leaf with dark green areas. Later on, the mosaic becomes stronger, and vein banding appears. Leaves can be deformed to shoestring appearance, but the most affected are fruits, that are severely malformed and often develop longitudinal cracks (**Figure 4**). Similarly, squash and pumpkin plants develop knobby areas on the fruits resulting in prominent deformations. In watermelons, as in melons, ZYMV induces yellow mosaic, severe malformations of leaves and fruits, that often display radial or longitudinal cracks. On cucumber, symptoms of ZYMV infection are less severe than on the other cucurbit crops; mosaic of variable intensity, followed by dark green vein banding and discoloration of fruits.

Vesicular Stomatitis Virus

S P J Whelan, Harvard Medical School, Boston, MA, USA

© 2008 Elsevier Ltd. All rights reserved.

Historical Perspective

Vesicular stomatitis viruses (VSVs) are transmitted naturally by arthropods to a broad range of animal species. A clinically significant acute disease is manifest in domesticated animals, notably cattle, horses, and pigs, and it is characterized by fever and the appearance of vesicular lesions in the mouth, tongue, udder teats, and hoof coronary bands. Symptoms are therefore similar to those following infection with the apthovirus, foot-and-mouth disease virus (FMDV) and, consequently, rapid diagnosis is important in livestock. VSV infection was first described in the USA in 1916, following an epidemic in cattle and horses. However, reports from 1862 describe a clinically similar disease in army horses during the American Civil War. Today the virus is distributed throughout the Americas and is enzootic in Central America. In Panama, estimates suggest that up to 29% of the human population has been exposed to the virus as judged by the presence of neutralizing antibodies. Infection of humans can result in a mild febrile illness, but is generally asymptomatic. VSVs have been described rarely outside the Western Hemisphere.

Taxonomy and Classification

VSVs have a nonsegmented negative-sense RNA genome and are assigned to the order *Mononegavirales*. Within this order, they are assigned to the family *Rhabdoviridae,* based upon their characteristic 'bullet' shape. Within the rhabdovirus family, they are further assigned to the genus *Vesiculovirus*. A list of the nine currently recognized species assigned to the genus is provided in **Table 1**, along with their geographic distribution and sources of the virus in nature. The *Eighth Report of the International Committee on the Taxonomy of Viruses* lists an additional 19 members tentatively assigned to this genus. The type species is *Vesicular stomatitis Indiana virus*. Vesicular stomatitis Indiana virus (VSIV) has been widely studied in laboratories as a prototype of all the *Mononegavirales* and will be the primary focus of this article. Much is known about the replication and molecular biology of VSIV. VSIV was isolated following an outbreak of a vesicular disease of cattle in Richmond, Indiana, in 1925. The infectious agent was maintained by serial passage in animals and eventually became the Indiana serotype of VSV. *Vesicular stomatitis New Jersey virus* is also classified as a species in the genus *Vesiculovirus*. It was isolated following an outbreak in cattle in 1926 and is serologically and genetically distinct from VSIV. Vesicular stomatitis Alagoas virus (VSAV) was isolated from domesticated animals in Alagoas Brazil during an outbreak of VSV.

Structure of VSV

Particles

A schematic of VSIV is shown in **Figure 1** along with an electron micrograph showing virus particles. The particles appear bullet-shaped and are approximately 180 nm long and 70 nm in diameter. The particles comprise 74% protein, 20% lipid, 3% RNA, and 3% carbohydrate. The virus possesses a lipid envelope that is decorated with trimeric spikes of the 67 kDa attachment glycoprotein (G). The interior of the particle contains a ribonucleoprotein (RNP) core of the genomic RNA complexed with the viral nucleocapsid (N) protein. This N-RNA core is associated with the RNA-dependent RNA polymerase (RdRp), the viral components of which are a 241 kDa large (L) protein and a tetramer of a 29 kDa accessory

phosphoprotein (P). Together, these form the internal helical nucleocapsid. Another major structural component of the virus particles is the 26 kDa matrix (M) protein, which is located below the membrane and associated with the nucleocapsid. The approximate composition of the particle is one molecule of RNA, 1200 copies of N, 500 copies of P, 1800 copies of M, 1200 copies of G, and 50 copies of L. The role of these proteins in viral replication is described in more detail below.

Genome

VSIV has a nonsegmented, negative-sense RNA genome of 11 161 nt. The genome comprises a 50 nt 3′ leader region (le), five genes that encode in order the N, P, M, G, and L proteins, and a 59 nt 5′ trailer region (**Figure 2**). The 5′ and 3′ ends of the genome are not modified and contain a 5′ triphosphate and 3′ hydroxyl. A key feature of all mononegaviruses is that the RNA genome is not found naked within infected cells. Instead, it is present as a ribonucleoprotein complex, in which it is completely covered by the viral nucleocapsid protein. This N-RNA template, associated with the viral L and P proteins, comprises the transcription-competent core of the virus, and delivery of this complex is required to initiate the infectious cycle. Consequently, in contrast to positive-sense RNA viruses, the naked RNA is not infectious.

Viral Replication Cycle

The replication cycle (**Figure 3**) should be considered a continuum of events. However, it is convenient to divide the cycle into the following three stages.

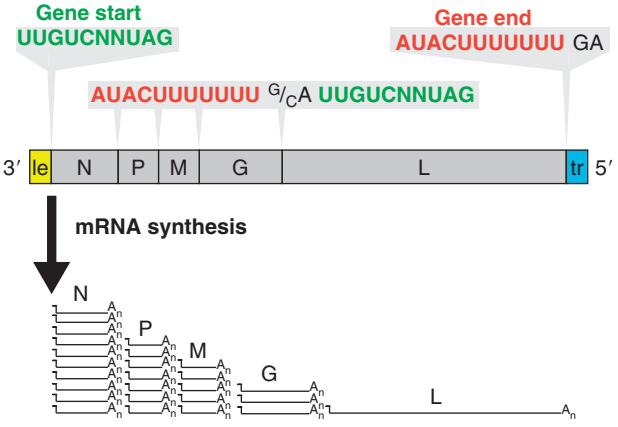

Figure 2 A schematic illustration of the VSIV genome highlighting the polymerase regulatory elements. The genome is represented 3′–5′ as a series of boxes, comprising le = leader region, N = nucleocapsid, P = phospho, M = matrix, G = glyco, L = large polymerase, and tr = trailer region. The conserved *cis*-acting elements that regulate polymerase activity during mRNA synthesis are shown for emphasis. Colors: green, the conserved residues of the gene-start sequence; red, the conserved residues of the gene-end sequence; and black, the nontranscribed residues of the gene junction. The leader and trailer regions also contain key elements that regulate polymerase activity and serve as promoters as described in the text.

Attachment, Entry, and Uncoating

Attachment of VSV to host cells is mediated by the glycoprotein which binds to the surface of cells. Given that VSV G can mediate infection of almost all cells in culture, either the receptor for VSV must be widely distributed, or the virus may be able to utilize multiple surface molecules for attachment. Phosphatidylserine (PS) was long thought to be the receptor for VSV but

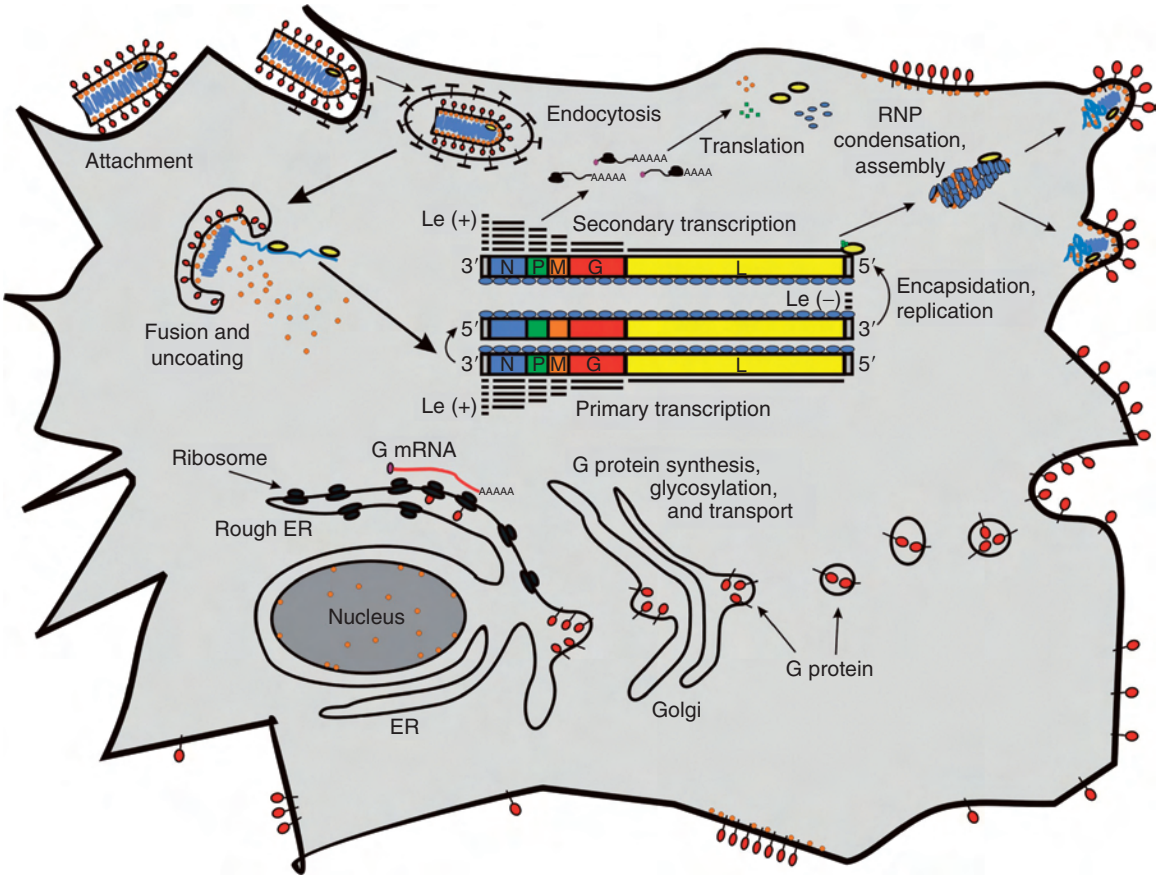

Figure 3 A schematic illustration of the replication cycle of VSV. The replication cycle (described in the text) is depicted showing attachment of virus to the cell, internalization, release of the viral core into the cytoplasm, primary viral mRNA synthesis, mRNA translation, genomic replication, secondary viral mRNA synthesis, assembly, and budding of infectious particles. Kindly provided by David Cureton, Harvard Medical School.

recent studies have questioned this finding. Importantly, the PS binding site in VSV G is internal to the trimer in its prefusion form. Following attachment to the cell, the virus is internalized via clathrin-dependent endocytosis and delivered to an early endosome. The pH threshold necessary to trigger the conformational alterations in VSIV G that promote fusion of the viral and cellular membranes is approximately 6.2. This pH is reached in the early endosome, and viral and cellular membranes fuse to release the transcription-competent RNP core into the cytoplasm of the cell. Recent work has called into question this conventional view of the VSV entry pathway and has posited a new model for viral entry. In this model, fusion and RNP release are spatially and temporally separated. Specifically, the low pH encountered during endocytic transport triggers fusion and the delivery of the RNP core into an intralumenal vesicle within an endosomal carrier vesicle. A subsequent (cell-mediated) fusion event is then required to fuse the membrane of the intralumenal vesicle with the limiting membrane of the cell and deliver the RNP into the cytoplasm to initiate the infectious process. Irrespective of the precise route by which virus enters the cell, the end result is the delivery of the transcription-competent core into the cytoplasm. This is accompanied by the release of M protein, which can migrate to the nucleus where it plays a role in inhibiting host gene expression.

Gene Expression

Following the delivery of the transcription-competent core into the cytoplasm, RNA synthesis can begin. The replication cycle of VSV is entirely cytoplasmic, occurring efficiently in enucleated cells. The demonstration that purified VSV particles contain a functional RdRp that is active *in vitro* has led to major advances in our understanding of viral gene expression. During RNA synthesis, the polymerase uses the encapsidated genomic RNA as template in two distinct reactions: (1) transcription of five mRNAs that encode the N, P, M, G, and L proteins; and (2) replication to yield full-length antigenomic, and then genomic RNA strands. Our current

understanding of gene expression is summarized as follows. In response to a specific promoter element that is provided by sequences within the 3′ leader region and the conserved residues of the first (N) gene-start (3′-UUGUCNNUAG-5′) sequence, the RdRp initiates mRNA synthesis. Synthesis commences at the N gene-start sequence and generates an mRNA that is capped, methylated, and polyadenylated, each of these reactions occurring co-transcriptionally. Termination at the end of the N gene is achieved by the polymerase recognizing a highly conserved sequence element referred to as the gene-end 3′-AUACUUUUUUUG/C-5′. This sequence signals the polymerase to stutter on the U_7 tract to generate the polyA tail, and leads to termination of mRNA synthesis. Termination at the end of the N gene is essential for the polymerase to be able to transcribe the P gene. A poorly understood event that is localized to a short region at the N–P gene junction results in the synthesis of approximately 30% less P mRNA than N mRNA. This sequential and polar synthesis of the viral mRNAs continues through the entire genome and provides a gradient of viral mRNA synthesis such that N > P > M > G > L. These products of mRNA synthesis are illustrated in **Figure 2**.

Among the notable steps of mRNA synthesis are the unusual mechanisms by which the 5′ and 3′ ends of the RNA are formed. Each stage of mRNA cap formation is distinct from those employed in other systems. Specifically, the 5′ end of the pppApApCpApG mRNA is capped by an unusual ribonucleotidyltransferase activity that transfers the monophosphate RNA onto GDP derived from GTP to form the *G*pp*p*ApApCpApG mRNA cap structure. In contrast, all other capping reactions are catalyzed by an RNA guanylytransferase that transfers GMP onto the 5′ end of a diphosphate RNA through a reaction that involves a covalent enzyme GMP intermediate. The VSV L protein is responsible for this novel reaction, which appears to involve a covalent intermediate between L and the viral mRNA. The resulting *Gpp*pApApCpApG cap structure is then methylated at guanine N-7 and ribose 2′-O positions to yield 7^{m}G*pp*pA^{m}pApCpApG. These activities are also provided by the L protein, and again differ from conventional mRNA cap methylation reactions. For VSIV, the two enzymatic activities have been shown to share a single binding site for the methyl donor, *S*-adenosyl-L-methionine (SAM). In contrast, other cap methylation reactions are normally executed by two distinct proteins with separate binding sites for the methyl donor SAM. Formation of the 3′ end of the RNA is also unusual. Specifically, polyadenylation occurs in a pseudo-templated fashion in which the polymerase complex reiteratively transcribes the conserved U tract present at the end of each VSV gene.

The viral mRNAs are efficiently translated by the host translation machinery, but how they compete with cellular mRNAs for translation is not well understood. Viral protein synthesis is essential for replication of the genomic RNA. Ongoing translation provides a continuous supply of soluble N protein that drives the encapsidation of the nascent RNA chain. This process is intimately linked to genomic RNA replication which first results in the production of a full-length encapsidated complementary antigenome RNA. This antigenome can then serve as template to produce more progeny genomic RNAs for use as templates for further mRNA synthesis in a process referred to as secondary transcription.

Precisely how the different polymerase activities are regulated in infected cells remains poorly understood. Two functionally distinct pools of polymerase have been purified from cells. One initiates internally at the N gene-start sequence and functions as the viral transcriptase. A second complex initiates at the 3′ end of the genome and functions as the viral replicase. These complexes are reported to differ in their composition such that the transcriptase comprises the viral P and L proteins, together with several cellular proteins including translation elongation factor-1α, heat shock protein 60, and the host cell RNA guanylyltransferase. In contrast, the replicase is reported to comprise the viral N, P, and L proteins.

In addition to the species of RNA described above, two short leader RNAs are generated during RNA synthesis: a 47 nt Le+ from the 3′ end of the genomic RNA and a 45 nt Le– from the 3′ end of the antigenomic RNA. The function of these RNAs is poorly understood, although a role for the Le+ in the shutoff of host gene expression has been described. A long-standing model for the regulation of RNA synthesis in VSV postulates that polymerase initiates all RNA synthesis at position 1 of the genome, and during synthesis of Le+ a crucial regulatory decision is made to either terminate leader and initiate mRNA synthesis at the N gene start, or alternatively to read through the leader–N gene junction and synthesize the full-length antigenome. The obligatory requirement for protein synthesis to provide a source of N protein to encapsidate the nascent RNA during genome replication led to the suggestion that N protein availability switches polymerase activity from transcriptase to replicase.

In recent years, there has been an accumulation of evidence that conflicts with this model. Specifically, a VSV mutant containing a single amino acid change in the template-associated N protein produces an excess of N mRNA over Le+ *in vitro*, suggesting that polymerase can synthesize N independently of Le+. In another series of experiments, recombinant VSVs, containing a 60 nt gene inserted between the leader region and the N gene, were employed. The recombinant viruses were examined to determine the effect of altering the potential number of

ultraviolet (UV)-induced dimers between adjacent uracil residues. Such dimers block progression of the polymerase. These experiments showed that changing the UV sensitivity of the Le+ had no effect on the sensitivity of the 60 nt mRNA in infected cells, suggesting that polymerase can initiate synthesis internally at the first gene start. In addition, two separate pools of polymerase can be isolated from infected cells, one that initiates internally at the N gene start and the second that initiates at the 3′ end of the genome. These findings support the hypothesis that mRNA synthesis can initiate independently of leader synthesis, and show that polymerase function is not simply switched by N protein levels. However, viral gene expression is controlled, it results in the exponential amplification of the input genomic RNA, yielding progeny genomes that can be assembled into infectious particles, the next phase of the viral replication cycle.

Assembly and Budding

Assembly of infectious virus particles involves many critical interactions. Our current understanding of this intricate process is that the matrix (M) protein complexes with the RNP core and represses transcription of viral mRNAs. This condensed RNP complex acquires a lipid envelope that has been modified by the insertion of an externally oriented glycoprotein. Details of how the RNP is transported to the site of budding and how the matrix interacts with and condenses the RNP are poorly understood. The M protein is only found associated with RNPs at sites of viral budding, and how genomic RNPs (rather than antigenomic RNPs) are specifically selected for budding is unclear. The M protein contains two 'late domains' (PTAP and PPPY motifs) that appear to be critical in the late phase of the assembly-release pathway. Amino acid substitutions in the PPPY motif result in the accumulation of bullet-shaped virions that are stalled at a late stage of virus budding. This motif, and similar motifs in proteins from other enveloped viruses, target virus for budding through interaction with components of the endosomal sorting complex required for transport or ESCRT pathway. The release of infectious particles completes the replication cycle and provides progeny virions for infection of the next cell.

The kinetics of the viral replication cycle are rapid. In mammalian cells in culture, one infectious particle can produce 10 000 infectious progeny within 8 h. While much remains to be explored about the biology of VSV, it is one of the best understood animal viruses. Studies on VSV should continue to prove informative in understanding how enveloped viruses enter and bud from their host cells, and how nonsegmented negative-strand RNA viruses (mononegaviruses) express their genetic information.

Functions of the Viral Proteins

Nucleocapsid protein

The N protein coats the viral genomic RNA and the positive-sense antigenomic replicative intermediate to form ribonucleoprotein (RNP) complexes. The interaction with the N protein renders the RNA resistant to cleavage by ribonucleases. It is in this form that the RNA is presented to the polymerase to serve as template. The N protein comprises 422 amino acids and has a molecular weight of approximately 48 kDa. The crystal structure of a complex of 10 molecules of N protein bound to 90 nt of RNA has been solved, revealing that N has a bilobed structure with RNA bound between the lobes. The structure indicates that N protein must be either transiently displaced or substantially remodeled during copying of the RNA genome by the viral polymerase.

Phosphoprotein

P is a multiply phosphorylated acidic protein of 265 amino acids that functions as an essential polymerase cofactor and plays an additional role in maintaining N protein in a soluble form necessary for RNA encapsidation. Sequence analysis has identified three domains of P. An acidic N-terminal domain (domain I) of 150 amino acids contains phosphorylation sites at Ser 60, Thr 62, and Ser 64. Phosphorylation of these residues by the host casein kinase II leads to the oligomerization of P protein and together with the large polymerase protein L, assembly of the polymerase complex. Domain I is separated from domain II by a highly variable hinge region comprising residues 150–210. Domain II (residues 210–244) contains additional phosphorylation sites at Ser 226, Ser 227, and Ser 233 that appear to be important for RNA replication. Domain III is basic and comprises the C-terminal 21 amino acids. A crystal structure of a fragment comprising amino acids 107–177 of the P protein has been solved, providing evidence that P protein functions as a tetramer. In addition to P, two proteins (C and C′) are produced from the P gene. These proteins are small (55 and 65 amino acids, respectively), are highly basic, and have not been detected in virus particles. Recombinant viruses that are unable to produce C and C′ replicate normally in cultured mammalian cells. The role of these proteins is unclear but may be important for infections in insects and/or mammalian hosts *in vivo*.

Matrix protein

The matrix (M) protein is the major structural component of virus particles. M is a small 229-amino-acid multifunctional protein. It condenses viral RNPs and drives budding of virus particles from the host plasma membrane. In addition, M downregulates host gene expression by directly interacting with Rae 1, thus inhibiting nuclear transport. The crystal structure of amino acids 48–229 of

the matrix protein has been solved and reveals regions of M that may be required for membrane association. Two N-terminal truncations of M are generated in infected cells by initiation of translation at methionines 33 and 51. A recombinant virus engineered to ablate the expression of these two alternate forms of M shows a modest reduction in cytopathic effect in culture cells.

Glycoprotein

The attachment glycoprotein (G) is a trimer present on the surface of the virion. It is responsible for attachment of virus to cells and promotes fusion of the viral and cellular membranes during endocytosis. The protein is synthesized as a 511-amino-acid polypeptide that is co-translationally inserted into membranes in the endoplasmic reticulum (ER). An N-terminal 16-amino-acid signal sequence is cleaved from the nascent polypeptide upon insertion. A 20-amino-acid hydrophobic sequence acts as the membrane anchor and serves as a stop-transfer signal during ER translocation. The remaining 29 amino acids of G remain as a cytoplasmic tail. Co- and post-translational modifications result in N-glycosylation of two asparagine residues in the ectodomain, and palmitoylation of a cysteine in the cytoplasmic domain. The role of palmitoylation in infection is unclear as some VSV strains lack this modification. However, glycosylation permits association of G with calnexin, an ER-resident chaperone, and mutations that prevent glycosylation result in G protein aggregation. Mature G protein is selectively transported to the basolateral surface of polarized epithelial cells. At the plasma membrane, VSV G clusters in microdomains that are the sites of virus assembly and budding. The determination of the crystal structure of a fragment of the G protein in both pre- and postfusion conformations has provided new insight into the entry process. The structures show that each G protein monomer contains two hydrophobic fusion loops that insert into the target cell membrane. Substantial rearrangements of the G protein that are driven by the low pH environment encountered in the endocytic pathway drive fusion of the viral and cellular membranes.

Large polymerase protein

The large polymerase protein (L) comprises 2109 amino acids. This 241 kDa multifunctional protein is responsible for template binding, ribonucleotide polymerization, and the co-transcriptional modification of the 5′ and 3′ terminus of the viral mRNAs so that they are capped and methylated. To date, structures are not available for any portion of the L protein. Amino acid sequence alignments of the L genes of representative members of the families *Rhabdoviridae*, *Paramyxoviridae*, and *Filoviridae* have led to the identification of six regions of sequence conservation (CRI–CRVI), separated by regions of no or low sequence homology. These conserved regions are thought to represent the functional domains of L protein. CRIII contains clearly identifiable motifs found in all polymerases and in which alterations to a universally conserved aspartic acid residue eliminate polymerase activity in reconstructed RNA synthesis assays. CRVI functions as a messenger RNA cap-modifying enzyme. Amino acid substitutions to this region disrupt mRNA cap methylation at both the guanine N-7 and ribose 2′-O positions of the cap structure. The regions of L involved in other modifications have not yet been assigned. As described above, L protein has been reported to associate with a number of host proteins, including translation elongation factor-1α, heat shock protein 60, and the host RNA guanylyltransferase. However, the functional significance of these interactions is not yet certain.

Host Range and Transmission

In nature, VSVs can infect a broad range of animals including mammals and invertebrates. Overt disease is typically only seen in cattle, horses, and swine, but there is evidence of natural infection in a range of wild ruminants, ungulates, carnivores, marsupials, and rodents. Infection can be transmitted directly from animal to animal, but this requires an abrasion or a means of introducing the virus below the skin. Humans can also be infected by contact with vesicular lesions or the saliva of infected animals, resulting in an influenza-like illness. Aerosol transmission has also been reported in humans. Insect vectors appear to be important in natural transmission of the virus. VSVs have been isolated on more than 40 occasions from hematophagous insects including mosquitoes, biting midges (*Culicoides* spp.), phlebotomine sand flies (*Lutzomyia* spp.), and black flies (*Simulium* spp.). In addition, VSV has been experimentally transmitted to mice from infected mosquitoes and between insects through co-feeding. Susceptible insect hosts are also capable of transovarial transmission and these infected progeny have been shown to infect mammalian hosts. Recovery of vesicular stomatitis New Jersey virus (VSNJV) from non-biting flies suggests that mechanical transmission may occur. There is also evidence that grasshoppers (*Melanoplus sanguinipes*) can be infected experimentally, and cattle that ingest infected grasshoppers can develop disease.

Consistent with the ability to infect a broad range of experimental animals, VSV replicates efficiently in a variety of cell lines of vertebrate and invertebrate origin. The Syrian hamster kidney cell line, BHK-21, is commonly used to generate viral stocks of high titer (10^9–10^{10} pfu ml^{-1}). VSV can also infect and replicate to high titers in cultured cells derived from insects, reptiles, and fish, and replication can occur in several insect cell lines. Infection of mammalian, avian, and some insect cells results in a cytopathic effect (CPE). In fibroblasts, this is

seen as an increase of membrane blebbing followed by extensive cell rounding. The M protein is responsible for these changes in infected cells. A noncytopathic infection occurs in some insect cells including lines derived from *Aedes aegypti*, *Aedes albopictus* (C6/36), and *Drosophila melanogaster*. Experimentally, the virus has been shown to express its genetic information in spheroblasts derived from the yeast, *Saccharamoyces cerevisae*, and to produce infectious virions in embryonic cells derived from the nematode *Caenorhabditis elegans*. Thus, the host requirements for viral replication are provided by an extremely broad range of eukaryotes.

Evolution

Several principles of evolutionary biology have been explored using VSV as a model system. The viral polymerase has an error rate of 10^{-3} to 10^{-5} per nucleotide per round of replication. Given the genome size is 11 161 nt, each time the genome is copied, on average, at least one nucleotide change is introduced. These mutations are typically deleterious, others will be neutral, and some may offer a selective advantage. Consequently, this high mutation rate contributes to VSV's ability to rapidly evolve and adapt to environmental changes. The high mutation rate also begs the question as to why VSV does not mutate itself out of existence. Rather than existing as a single defined sequence, the virus exists as a swarm of mutant sequences around a consensus sequence or a viral quasispecies. Critically, it is this quasispecies that is the biologically relevant target for selection.

Experiments in which the diversity of the viral population is artificially restricted by performing serial plaque-to-plaque transfers (thus restricting the infectious virus population to 1 on each transfer), rapidly result in fitness losses. Such an accumulation of deleterious mutations in populations of asexual organisms lacking compensatory mechanisms such as sex or recombination was predicted by Muller in a concept referred to as Muller's ratchet. This principle has been nicely illustrated in studies of VSV, which is not known to undergo homologous recombination. Studies with VSV have also illustrated other fundamental principles of population genetics. Work by the laboratory of John Holland demonstrated that VSVs of equal fitness could coexist for several generations, but one population would then rapidly outgrow the other. This demonstrated that populations accumulate mutations and, infrequently, mutations provide a selective advantage which leads to its outgrowth. Importantly, the mutation rates in both populations were the same, reflecting an intrinsic property of the viral polymerase. This is referred to as the Red Queen effect. This is a hypothesis proposed by the evolutionary biologist Leigh van Valen in reference to Lewis Carroll's book *Through the Looking Glass*, in which the Red Queen comments to Alice that "it takes all the running you can do, to keep in the same place."

Despite the intrinsically high polymerase error rate, VSVs isolated in nature can show a remarkable genetic stability. For example, sequence analysis of viruses from different hosts and different years has shown that those isolated from multiple hosts within the same region over a period of decades were more closely related than viruses isolated in the same year, but from a different ecological zone. This suggests that ecological factors are a major driving force in the evolution of VSV. Consistent with this, viruses from similar ecological zones 800 km apart were found to be more closely related than viruses from different ecological zones 25 km apart. VSV evolution is unusual in this apparent lack of a 'molecular clock' in which the genome sequence does not show a clear relationship with year of isolation.

The evolutionary origins of VSVs are uncertain but the conservation of gene order and sequence similarity to other members of the *Mononegavirales* indicate they diverged from a common ancestor. Although the number of genes differ, their order is maintained across the *Mononegavirales* as 3′ N–P–M–G–L 5′. The significance of this gene order has been elegantly tested in engineered VSIV recombinants by shuffling the order of the three central genes (P, M, and G), and by moving the N and G genes. Remarkably, all gene orders yield infectious virus, and the replication kinetics of several recombinant viruses in which the P, M, and G genes were shuffled were similar to those of the wild-type parent virus. Consistent with its critical role in driving RNA encapsidation during genome replication, moving the N gene from its promoter proximal position diminished viral replication. These experiments suggest that the conserved gene order may reflect an ancestral gene order that has remained frozen because of the lack of a mechanism for homologous recombination in the *Mononegavirales*.

Geographic and Seasonal Distribution

VSVs are typically restricted to the Americas. Within this region, VSIV and VSNJV are the two most commonly isolated serotypes and have the broadest geographic distribution ranging from Peru to Canada. Vesicular stomatitis Alagoas virus (VSAV) is the major serotype that is isolated in Brazil. Both VSIV and VSNJV are seen in the United States although most outbreaks are associated with VSNJV. In the US, the last outbreak was from 2004 to 2006. In this outbreak, viral infection was reported in Texas, New Mexico, and Colorado in 2004, and the outbreak spread to include Arizona, Utah, Wyoming, Nebraska, Montana, and Idaho in 2005, with a small number of cases reported in Wyoming in 2006. Overall some 1000 animals were affected, representing the most significant outbreak

of disease in the US for almost 10 years. Vesicular stomatitis is endemic in many Latin American countries. In 2002, VSNJV and VSIV were reported in Panama, Costa Rica, Nicaragua, El Salvador, and Mexico, and VSNJV was reported in Honduras, Guatemala, and Belize. In 2004, VSNJV and VSIV were isolated in Columbia, Venezuela, Ecuador, and Peru, and VSIV in Brazil and Bolivia. Although infection is reported throughout the Americas, the highest incidence usually is in tropical regions with more sporadic outbreaks in temperate regions. In temperate regions, outbreaks typically peak in late summer and end by the first frost. In tropical regions, peak incidence typically coincides with the end of the rainy season. These peaks correlate with high insect population levels and, consistent with the role of insect vectors in disease spread, outbreaks tend to spread along waterways. Although, on occasion, VSV has been reported in parts of Europe and Africa, such reports are rare and are probably linked to importation of infected animals.

Pathogenesis and Pathology

Following exposure of animals to VSV, the incubation period is usually 2–4 days. Prior to the development of lesions, animals can show signs of depression, lameness, a fever of up to 41.5 °C, and excessive salivation. In infected cattle, swine and horses, pink to white papules appear in the mouth, lips, gums, nose, teats, and feet. In these regions, the epithelium separates from the basal layer forming a vesicle that fills with clear yellowish fluid that contains very high titers of infectious virus. These vesicles combine and readily rupture. In some cases, lesions appear at a secondary site relative to the initial point of inoculation. The development of secondary lesions is suggestive of a viremia, but virus has not been isolated from the blood of experimentally inoculated natural hosts. Infection results in significant losses for the livestock industry as weight loss can be significant (up to 135 kg in beef cattle), and dairy cattle usually cease milk production. In the absence of secondary infections, the vesicular lesions typically heal in 1–2 weeks and the animals start to regain weight. Viral RNA has been isolated from animals several months after infection although infectious virus has not been recovered.

Immune Response

Our understanding of the immune response to VSV in natural hosts is limited. However, in experimental animals, notably mice, the immune response to VSV has been characterized. Interferon plays an important role in the resistance of older mice to VSV infection and, consistent with this, adult mice that are unable to produce interferon succumb to infection. Different strains of VSV induce different levels of interferon, but there is no clear correlation between levels of interferon *in vitro* and pathogenesis in animals. Neutralizing antibody has also been shown to play a role in the defense against VSV infection in experimentally infected swine and mice. The target of these neutralizing antibodies is the viral attachment protein G, and adoptive transfer experiments have shown that they are sufficient to protect young mice against infection. In endemic areas, susceptible hosts often have detectable neutralizing antibody responses to VSV. However, these responses are not protective, perhaps reflecting the fact that viral replication is largely confined to the epithelium. Experimental infection of mice with VSV also induces a strong cytotoxic T-lymphocyte (CTL) response. The N protein is the predominant antigen recognized and the resulting CTLs are not serotype specific. However, the functional significance of these CTLs in protection against infection is uncertain as mice incapable of mounting such a response survive VSV infection.

Diagnosis, Prevention, and Control

The similarity of symptoms between VSV and FMDV make rapid diagnosis important, especially in countries that are free of FMDV. Diagnosis is achieved typically by analysis of samples of fluid from vesicular lesions using reverse transcription-polymerase chain reaction (RT-PCR), enzyme-linked immunosorbent assay (ELISA), or growth of virus in cell culture. VSV is listed as a notifiable disease by the World Organisation for Animal Health (OIE) and a positive diagnosis results in quarantine of the affected area. To control spread of disease, farm equipment is disinfected using a 2% bleach solution to interrupt animal-to-animal spread, and insect control measures can be introduced. Vaccines against VSIV and VSNJV have been used to control outbreaks in Central and South America. Although vaccination is not routinely practiced throughout the Americas, experiments demonstrate a substantive decrease in clinical infections in vaccinated animals.

Future Perspectives

VSVs will continue to serve as an important prototype of the nonsegmented negative-strand RNA viruses. The advantages of VSV as a model for these viruses are: (1) its relative safety, in that the virus is not a significant human pathogen; (2) abundant viral replication in a broad range of cultured cells yielding up to 10 000 pfu $cell^{-1}$ 8–12 h post inoculation of mammalian cells; (3) a robust reverse genetic system which permits the generation of helper-dependent viruses; (4) crystal structures of the N-RNA template, a portion of the P and M proteins,

and the pre- and postfusion forms of the G protein; and (5) an *in vitro* system for viral mRNA synthesis using purified recombinant polymerase. Capitalizing on these advantages will continue to provide new mechanistic insights into the molecular details of viral entry, gene expression, and assembly. Among the key questions to address are understanding: (1) how and where the viral RNP core enters a cell; (2) how and where the N-RNA serves as template for gene expression; (3) how the large multifunctional polymerase serves to initiate, cap, methylate, polyadenylate, and terminate mRNA synthesis in response to specific sequence elements; (4) how the activities of the polymerase are controlled between mRNA synthesis and genome replication; and (5) how the nucleocapsid templates are selected for assembly and budding from the cell. In addition to the fundamental questions regarding the molecular biology of these viruses, the future holds promise for unraveling the significance of the different host species and vectors in the biology of infection. Genomic approaches will likely yield clues as to how VSV interacts with host cells of insect and mammalian origin, and how these cells respond to infection. Many questions remain to be answered regarding the ecology of the virus including the maintenance of the virus, its transmission, and its relative genetic stability in nature. Such studies are not only warranted in understanding VSV as a model virus, but also for the prospects of using VSV as an oncolytic virus and a live-attenuated vaccine vector for human disease. These potential applications should only add to the urgency with which studies on this prototypic virus are pursued.

Glossary

ER-associated degradation (**ERAD**) A cellular quality control mechanism ensuring efficient removal of misfolded and/or unassembled proteins from the endoplasmic reticulum (ER) lumen and their subsequent elimination by the cytoplasmic ubiquitin–proteasome system.
Heterokaryon Coexistence of two or more genetically different nuclei in a common cytoplasm.
Importins A family of proteins that transport macromolecules into the eukaryotic nucleus.
Killer virus system A killer virus system consists of a helper totivirus and a satellite double-stranded (ds) RNA encoding the unprocessed precursor of a secreted protein toxin that also gives functional immunity.
Preprotoxin Toxin precursor in the cytoplasm of a killer yeast which is post-translationally imported into the secretory pathway for toxin processing, maturation, and secretion.
Satellite dsRNA An encapsidated dsRNA that is dependent on a helper virus for encapsidation and replication.
Spheroplasts A yeast cell whose cell wall has been enzymatically removed.

Introduction

Although double-stranded (ds) RNA viruses had previously been identified in filamentous fungi, dsRNA viruses in yeast were discovered as determinants of the killer phenomenon in *Saccharomyces cerevisiae* and are now known to be associated with the presence of cytoplasmically inherited members of the totivirus family, which are frequently found in different yeast genera. Among these, the killers of *S. cerevisiae*, *Zygosaccharomyces bailii*, *Hanseniaspora uvarum*, and *Ustilago maydis* – the latter being the cause of corn smut – are best characterized. Characteristic for all killers is the secretion of protein toxins that are lethal to sensitive strains of different species and genera. Cell killing is usually achieved in a receptor-mediated process, requiring initial toxin binding to components of the outer yeast cell surface (such as β-1,6-D-glucans, α-1,3-mannoproteins, or chitin) and subsequent toxin transfer to a secondary plasma membrane receptor. Depending on the toxin, final lethality can be caused by plasma membrane damage, G1 or S phase cell-cycle arrest, and/or by rapid inhibition of DNA synthesis.

In the yeasts *S. cerevisiae*, *Z. bailii*, and *H. uvarum* as well as in the maize smut fungus *U. maydis*, the killer phenotype is cytoplasmically inherited and caused by an infection with dsRNA viruses of the family *Totiviridae* that are widely distributed among yeast and higher fungi. Since the majority of fungal mycoviruses are noninfectious and symptomless in the corresponding host, they are often classified as cryptic viruses or virus-like particles (VLPs). All known fungal viruses spread vertically by cell–cell mating and/or heterokaryon formation. In *S. cerevisiae*, diploids formed by mating of a killer with a sensitive strain are likewise killers, as are all haploid progeny of subsequent meiosis. In contrast, virus-free strains are usually sensitive nonkillers, while those containing ScV-L-A and a toxin-encoding M-dsRNA are killers (see below). Sensitive strains survive mating with killers, and cytoplasmic mixing of the multiple M-dsRNA copies during zygosis accounts for the inheritance pattern during meiosis. Extracellular spread of virions is generally hampered by the rigid yeast and fungal cell-wall barrier, and fungal viruses have adopted a strategy of transmission via mating and hyphal fusion (which occurs frequently in nature) making an extracellular route of spread dispensable. While some of these viruses can be associated with adverse phenotypic effects on the fungus (like La France disease in *Agaricus bisporus*, plaque formation in *Penicillium*, and hypovirulence in *Cryphonectria*), dsRNA viruses and their associated satellite dsRNAs in *S. cerevisiae*, *U. maydis*, *H. uvarum*, and *Z. bailii* are responsible for a killer phenotype which is based on the secretion of a polypeptide toxin (killer toxin) that is lethal to a variety of sensitive yeast and fungal strains. With the exception of toxin-secreting strains of *Z. bailii*, killer toxin production is usually associated with specific immunity, protecting the corresponding killer yeast against its own viral toxin.

dsRNA Viruses and Killer Phenotype Expression in *S. cerevisiae*

On the basis of killing profiles and the lack of cross-immunity, three major killer types (K1, K2, K28) have so far been identified in *S. cerevisiae*. Each of them produces a specific killer toxin and a self-protecting immunity component. Killer phenotype expression correlates with the presence of two types of dsRNA species stably persisting in the cytoplasm of the infected host: the genomic dsRNA of the helper virus, ScV-L-A, and one of three toxin-coding satellite dsRNAs that have been recognized so far (ScV-M1, ScV-M2, or ScV-M28). The ScV-L-A and M-dsRNAs are separately encapsidated into capsids encoded by ScV-L-A dsRNA and are present in high copy number in the yeast cell cytoplasm. *In vivo*, ScV-L-A does not confer a phenotype nor does it lead to host-cell lysis or slower cell growth. While the killer phenotype can be transmitted to sensitive yeast cell spheroplasts (harboring ScV-L-A) by transfection with an ScV-M preparation (either during mating or cotransformation with a dsDNA plasmid), extracellular transmission occurs rarely, if at all, in nature. The survival strategy adopted by these dsRNA viruses appears to be a balanced host interaction resulting in stable maintenance, little if any growth disadvantage, and vertical transmission. Mechanisms of exiting and entering the host cell through its tough and rigid cell wall are rendered unnecessary by relatively efficient horizontal transmission during the frequent zygosis events in yeast. Acquisition of a toxin-encoding M satellite dsRNA provides positive selection for both this dsRNA and ScV-L-A, since virus-free segregants are killed.

As summarized in **Table 1**, the linear dsRNA genome of ScV-L-A contains two open reading frames (ORFs) on its plus-strand RNA: ORF1 encodes the major capsid protein Gag necessary for encapsidation and viral particle structure, the second gene (ORF2) represents the RNA-dependent RNA polymerase Pol which is *in vivo* expressed as a Gag–Pol fusion protein by a –1 ribosomal frameshift event. In contrast to L-A, each M-dsRNA genome contains a single ORF coding for a preprotoxin (pptox) representing the unprocessed precursor of the mature and secreted toxin that also gives functional immunity. Since each toxin-coding ScV-M dsRNA depends on the coexistance of ScV-L-A for stable maintenance and replication, the killer viruses resemble classical satellites of ScV-L-A. Although the presence of all three M-dsRNAs with different killer specificities in a single cell is excluded at the replicative level of the M genomes, this limitation can be by-passed by introducing cDNA copies of the K2 and K28 pptox genes into a

Table 1 Members of the family *Totiviridae* involved in killer phenotype expression

Totivirus/satellite dsRNA	*Virus host*	*Function of virus*	*dsRNA (kb)*	*Encoded protein(s)*
ScV-L-A	*Saccharomyces cerevisiae*	Helper virus	L_A (4.6)	Gag, major capsid protein; Gag-Pol, RDRP[a]
ScV-M1	*Saccharomyces cerevisiae*	Satellite dsRNA	M_1 (1.6)	K1 preprotoxin
ScV-M2	*Saccharomyces cerevisiae*	Satellite dsRNA	M_2 (1.5)	K2 preprotoxin
ScV-M28	*Saccharomyces cerevisiae*	Satellite dsRNA	M_{28} (1.8)	K28 preprotoxin
UmV-H	*Ustilago maydis*	Helper virus	H (6.1)	Gag, major capsid protein; Gag-Pol, RDRP[a]
UmV-P1	*Ustilago maydis*	Satellite dsRNA	M_{P1}(1.4)	KP1 preprotoxin
UmV-P4	*Ustilago maydis*	Satellite dsRNA	M_{P4} (1.0)	KP4 toxin
UmV-P6	*Ustilago maydis*	Satellite dsRNA	M_{P6} (1.2)	KP6 preprotoxin
HuV-L	*Hanseniaspora uvarum*	Helper virus	L_A (4.6)	Gag, major capsid protein; Gag-Pol, RDRP[a]
HuV-M	*Hanseniaspora uvarum*	Satellite dsRNA	M_{Hu} (1.0)	KT470 toxin precursor
ZbV-L	*Zygosaccharomyces bailii*	Helper virus	L_{Zb} (4.6)	Gag, major capsid protein; Gag-Pol, RDRP[a]
ZbV-M	*Zygosaccharomyces bailii*	Satellite dsRNA	M_{Zb} (2.1)	prepro-zygocin

natural K1 killer, resulting in stable triple-killers producing three different virus toxins at a time and simultaneoulsy expressing triple-toxin immunity.

As typical for many dsRNA viruses, the replication cycles of ScV-L-A and M-dsRNAs depend on the presence of specific packaging signals at or near the 3′ end of the viral single-stranded RNA (ssRNA) transcript. These RNA regions function as viral binding sites (VBSs) and consist of a stem–loop structure whose stem is interrupted by an unpaired protruding A residue (**Figure 1**). For replication of L-A, two sequence elements are essential: an internal replication enhancer (IRE), which is essentially indistinguishable from the VBS, and a small stem–loop structure 5 bp from the 3′-terminus (3′-TRE). While L-A contains just a single VBS element, the toxin-coding transcripts of M1, M28, and M_{Zb} (encoding the *Z. bailii* viral toxin zygocin) each have two such VBS domains. *In vivo*, these VBS elements are *cis*-active sequences that are recognized by Gag–Pol and subsequently packaged into new viral particles. The replicase reaction on the (+)ssRNA template takes place *in viro* (i.e., within the viral capsid) and requires a correct 3′-end sequence and structure. Within the intact and mature virion, conservative transcription of the plus-strand from the dsRNA template requires recognition of its very 5′-terminal sequence by Gag–Pol. In M28 (as in other dsRNAs), the plus-strand initiates with 5′-GAAAA(A); since there are little additional conserved sequences immediately downstream, this terminal recognition element (5′-TRE) may be all that is necessary for transcription initiation (**Figure 1**).

Viral Replication Cycle

Yeast ScV-L-A virions are noninfectious icosahedral particles 39 nm in diameter that show certain similarities to mammalian reoviruses and rotaviruses. Each L-A virus consists of a single copy of the 4.6 kb L-A dsRNA genome which is encapsidated by 60 asymmetric dimers of the 76 kDa coat protein Gag and two copies of the 171 kDa Gag–Pol fusion protein. During conservative replication, the single-stranded plus-strand RNA (L-A(+)ssRNA) is transcribed within the viral particle (*in viro*) and subsequently extruded into the cytoplasm where it serves as (1) messenger RNA for translation into the viral proteins Gag and Gag–Pol and (2) RNA template which is packaged into new viral particles. Once this coat assembly is completed, Gag–Pol functions as replicase, synthesizes a minus-strand, and generates the dsRNA genome of the mature virus. The replication cycle of the toxin-coding M satellite dsRNA resembles that of L-A with the exception that each M virion can accept two copies of the smaller M-dsRNA genome before the ssRNA transcript is extruded into the cytoplasm; in analogy to certain DNA bacteriophages, this phenomenon has been named 'headful packaging'.

Viral Preprotoxin Processing and Toxin Maturation

In totivirus infected killer yeasts, the toxin-encoding M(+)ssRNA transcript is translated on free cytosolic ribosomes into a pptox precursor which is post-translationally imported into the secretory pathway for further processing, maturation, and toxin secretion. Interestingly, intracellular pptox processing in killer strains of either *S. cerevisiae* (K1, K2, K28), *Z. bailii* (zygocin), or *U. maydis* (KP4) is mechanistically conserved, resulting in the secretion of a biologically active monomeric or α/β heterodimeric virus toxin (**Figure 2**). In case of K28 killer strains containing ScV-M28, pptox is processed into a heterodimer whose α- and β-subunit is covalently linked by a single disulfide bond. Since the unprocessed toxin precursor resembles a secretory protein, it contains a hydrophobic

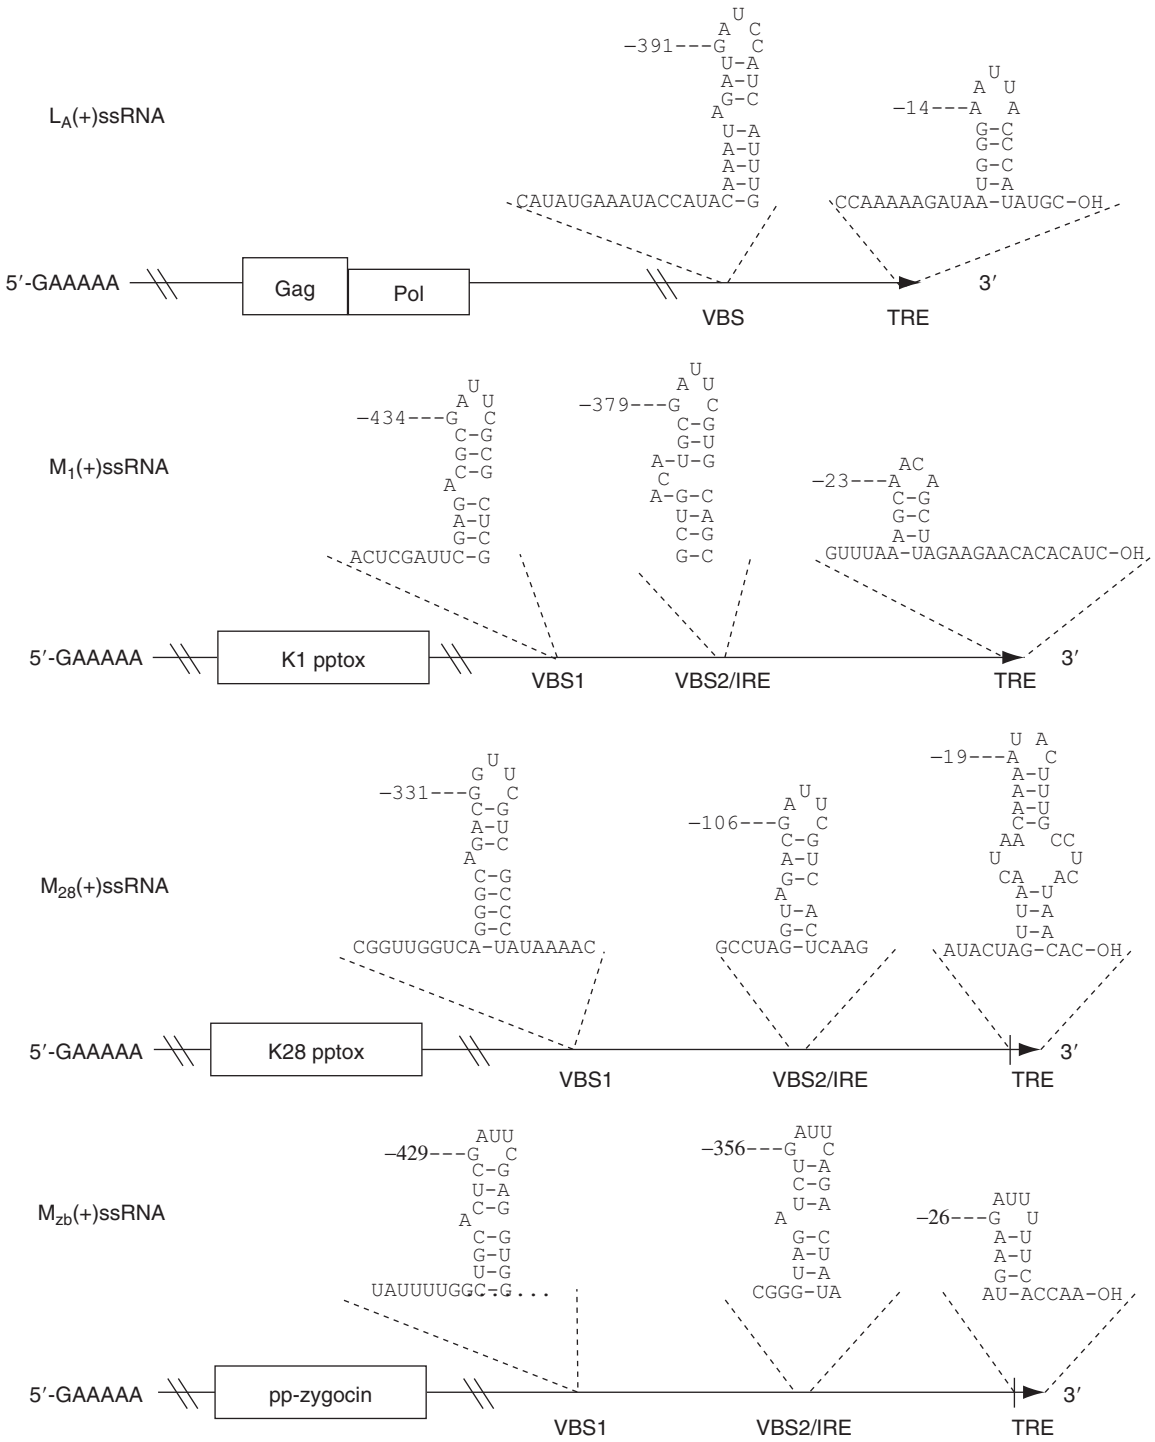

Figure 1 Comparison of the 5′- and 3′-ssRNA sequences in ScV-L-A and in the toxin-coding transcripts of the satellite ScV-M1, ScV-M28, and ZbV-M dsRNAs. Potential *cis*-active sequences within the 3′-termini are indicated (VBS, viral binding site; IRE, internal replication enhancer; TRE, 3′-terminal recognition element). Numbers are shown for distance from the 3′ end of each (+)ssRNA.

signal sequence for pptox import into the ER lumen followed by the toxin subunits α (10.5 kDa) and β (11.0 kDa) which are separated from each other by a potentially N-glycosylated γ-sequence (**Figure 2**). During passage through the yeast secretory pathway the K28 toxin precursor is enzymatically processed to the biologically active heterodimer in a way that is highly homologous to prohormone conversion in mammalian cells. In a late Golgi compartment, the N-glycosylated γ-sequence is removed by the action of the furin-like endopeptidase Kex2p, the

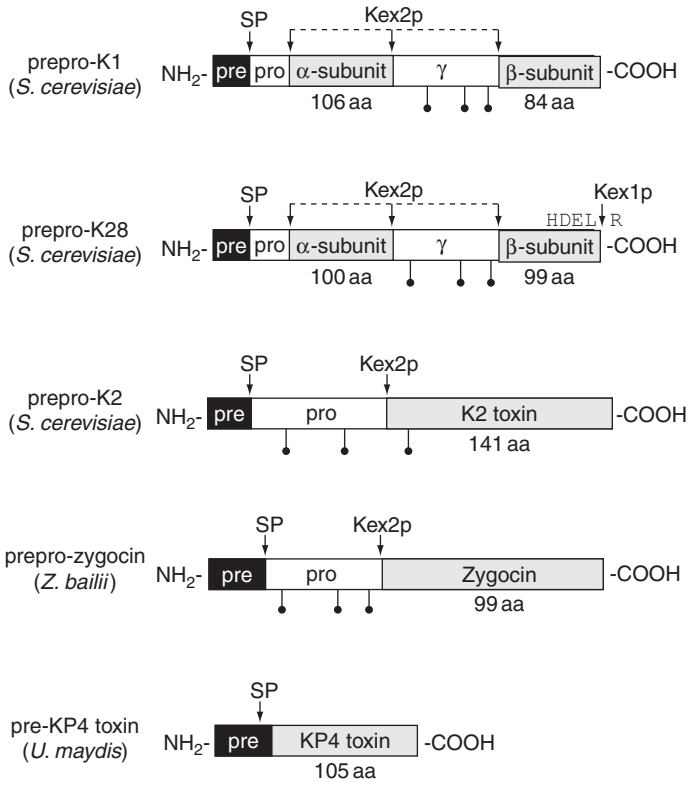

Figure 2 Analogy of toxin precursor processing in totivirus-infected killers of *S. cerevisiae*, *Z. bailii*, and *U. maydis*. Schematic outline of the precursor proteins (preprotoxins) encoding either a heterodimeric α/β toxin (K1, K28) or a monomeric virus toxin (K2, zygocin, KP4). Signal peptidase (SP) cleavage and Kex2p endopeptidase processing sites are indicated. Potential *N*-glycosylation sites are indicated with black circles (aa, amino acids).

C-terminus of β is trimmed by carboxypeptidase Kex1p cleavage, and the biologically active protein is secreted as a 21 kDa α/β heterodimer whose β-C-terminus carries a four-amino-acid epitope (HDEL) that represents a classical ER retention signal. Since this signal is initially masked by a terminal arginine residue (HDEL*R*), ER retention of the toxin precursor is prevented until the protoxin enters a late Golgi compartment where Kex1p cleavage uncovers the HDEL signal of the toxin (**Figure 3**).

Endocytosis and Intracellular Transport of the K28 Virus Toxin

In contrast to most virally encoded yeast killer toxins, which do not enter their host but rather kill a sensitive cell by disrupting plasma membrane function, K28 is taken up by receptor-mediated endocytosis and subsequently targeted to the secretory pathway. Once it has reached an early endosomal compartment, the toxin travels the secretion pathway in reverse and translocates into the cytosol. Responsible and essential for this retrograde transport is a short-amino-acid motif at the carboxyterminus of the K28 β-subunit (HDEL) which functions as ER targeting/retention signal that is normally present at the C-terminus of resident chaperones in the ER lumen such as Kar2p/BiP and Pdi1p, the protein disulfide isomerase. In yeast and higher eukaryotes, H/KDEL-carrying proteins are recognized by a membrane-bound H/KDEL receptor ensuring efficient recycling of H/KDEL-proteins from an early Golgi compartment back to the ER. In case of the K28 virus toxin, this sequence allows retrograde transport from early endosomes (via Golgi) to the ER from where the toxin enters the cytoplasm and transduces its lethal signal into the nucleus. Endocytotic uptake and retrograde transport is a common strategy realized in certain prototypes of bacterial toxins such as *Pseudomonas* exotoxin A, *Escherichia coli* heat-labile toxin (HLT), or even Shiga toxin. All these protein toxins are family members of microbial A/B toxins, which are usually internalized by receptor-mediated endocytosis, followed by reverse secretion via Golgi and ER. Interestingly, many of these toxins contain putative ER retention signals at their C-termini, and H/KDEL-dependent mechanisms have, therefore, been postulated to be of major importance for toxin entry into mammalian cells. In this respect, a major difference between the yeast K28 virus toxin and bacterial A/B toxins is that K28 itself

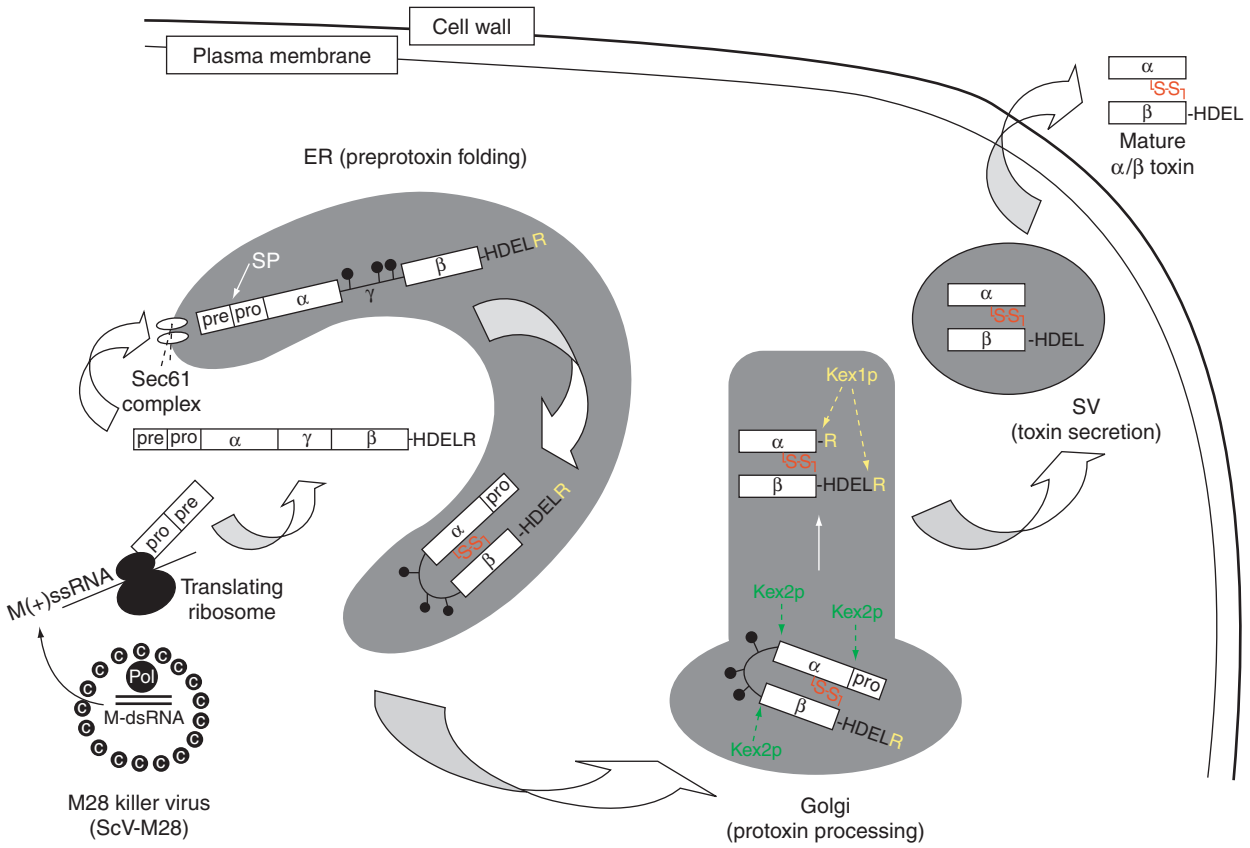

Figure 3 Preprotoxin processing and toxin secretion in an ScV-M28-infected killer yeast. After *in vivo* translation of the preprotoxin coding killer virus transcript, the toxin precursor is post-translationally imported into the endoplasmic reticulum (ER) through the Sec61 complex. Signal peptidase (SP) cleavage in the ER lumen removes the N-terminal signal sequence (pre-region) and protoxin folding is mediated by lumenal ER chaperones. The intervening γ-sequence is N-glycosylated and a single disulfide bond between α and β is generated. In a late Golgi compartment, Kex2p endopeptidase cleaves the pro-region, removes the γ-sequence, and carboxypeptidase Kex1p cleavage trimms the C-termini of both subunits, leading to the secretion of mature α/β toxin whose β-C-terminal HDEL motif is uncovered and thus accessible for interaction with the HDEL receptor of the target cell. SV, secretory vesicle. is produced and secreted by a eukaryotic (yeast) cell, and therefore the C-terminal ER-targeting signal in the toxin precursor is initially masked by a terminal arginine residue which ensures successful pptox passage through the early secretory pathway. Once the toxin has reached a late Golgi compartment, Kex1p cleavage removes the β-C-terminal arginine residue and thereby uncovers the ER targeting signal of the virus toxin. To ensure proper access of the ER targeting signal to the K/HDEL receptor of the sensitive target cell, many A/B toxins (including the yeast K28 virus toxin) contain a unique disulfide bond at or near the C-terminus. Consequently, mutant toxin variants with altered inter- and/or intra-subunit disulfide bonding are nontoxic *in vivo* due to the incapability to reach their intracellular target. Thus, disulfide bond formation in microbial and viral A/B toxins is of major importance to ensure interaction competence of the toxins with the K/HDEL-receptor of the target cell.

ER Exit and Nuclear Entry of the K28 Virus Toxin

During host-cell penetration, K28 retrotranslocates from the ER into the cytosol and dissociates into its subunit components. The β-subunit is subsequently polyubiquitinated and proteasomally degraded while the cytotoxic α-subunit enters the nucleus and causes cell death (**Figure 4**). ER exit of the α/β heterodimeric toxin is mediated by the Sec61 complex, termed translocon, which functions as major transport channel in the ER membrane of yeast and higher eukaryotes. In yeast, each translocon resembles a core heterotrimeric complex consisting of the transmembrane protein Sec61p and the two smaller subunits Sbh1p and Sss1p. Besides being the major channel for co- and post-translational protein import into the ER, Sec61p is also involved in the export and removal of malfolded and/or misassembled proteins from the secretory pathway to initiate their proteasomal

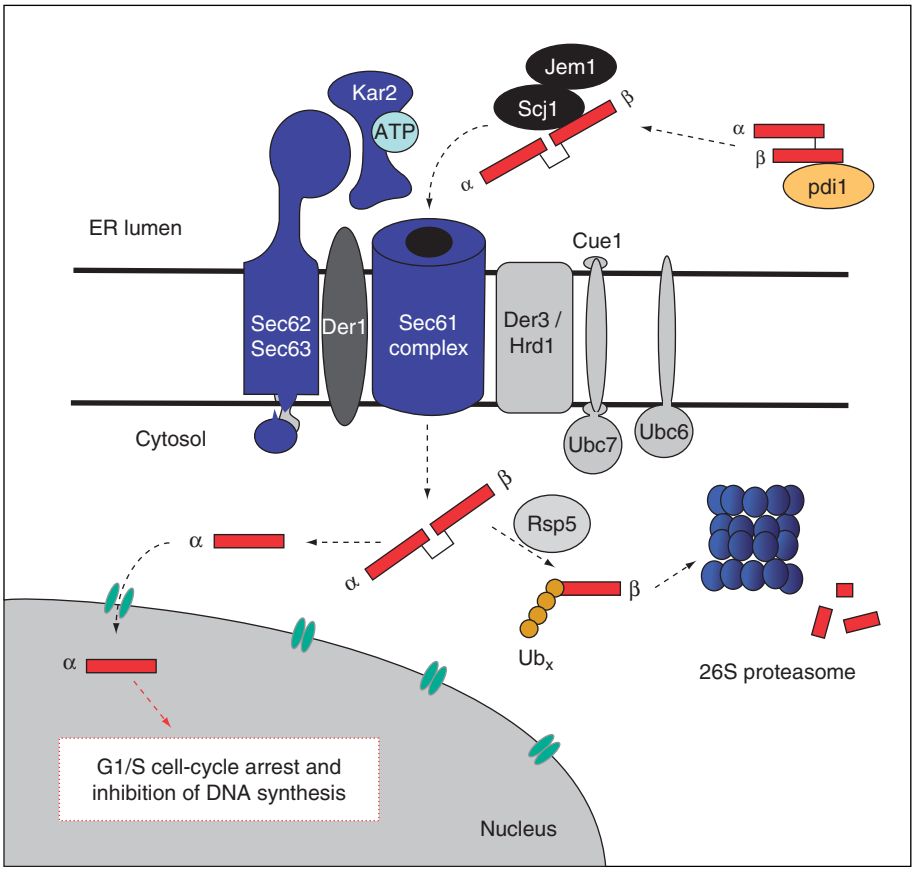

Figure 4 Retrotranslocation of the K28 virus toxin from the ER and its lethal effect in the nucleus. After endocytotic uptake and retrograde transport via Golgi and ER, the toxin is gated through the Sec61p export channel by the help of lumenal ER chaperones such as Pdi1p, Kar2p, Jem1p, and Scj1p. Within the cytosol, β is ubiquitinated and proteasomally degraded while α enters the nucleus and causes cell death. The α-toxin interacts with essential host proteins involved in eukaryotic cell-cycle control and causes cell death through G1/S cell-cycle arrest and inhibition of DNA synthesis. Cellular components of the ER quality control system ERAD (such as Cue1p, Ubc7p, Der3p/Hrd1p, Ubc6p, and Der1p) are not involved in ER-to-cytosol export of the K28 virus toxin (ERAD components are shown in gray color). Reproduced from Leis S, Spindler J, Reiter J, Breinig F, and Schmitt MJ (2005) *Saccharmyces cerevisiae* K28 toxin – A secreted virus toxin of the A/B family of protein toxins. In: Schmitt MJ and Schaffrath R (eds.) *Topics in Current Genetics 11: Microbial Protein Toxins*, pp. 111–132. Berlin, Heidelberg: Springer, with kind permission of Springer Science and Buisness Media.

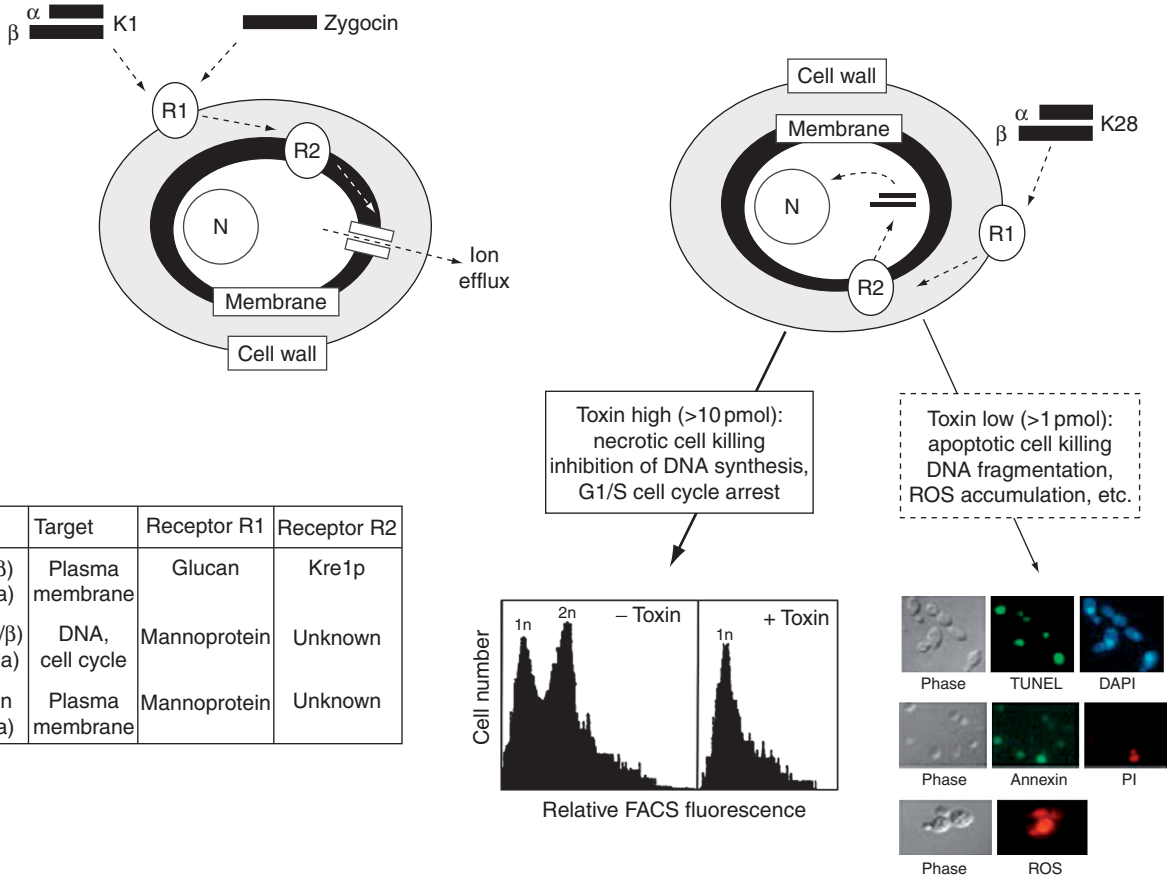
degradation in the cytosol. In addition to its central function in protein quality control in the ER, Sec61 is also responsible for ER retrotranslocation of certain plant, microbial and viral A/B toxins such as ricin, cholera toxin, *Pseudomonas* exotoxin A, and the yeast K28 virus toxin. In contrast to microbial and plant A/B toxins, however, retrotranslocation of K28 from the ER lumen is independent of ubiquitination and proteasome activity and classical components normally involved in ER-associated protein degradation (ERAD) are not required for ER exit of this virus toxin. In K28 intoxicated cells, toxin translocation competence in the ER strongly depends on the activity of lumenal Hsp70 chaperones (such as Kar2p/BiP and Pdi1p), Hsp40 cochaperones (such as Scj1p and Jem1p), and additionally requires proper maintenance of calcium homeostasis in the ER (**Figure 4**). So far it is not known what cellular component within or near the ER membrane is responsible for toxin exit, but K28 might be a fruitful tool to identify a novel transport pathway for protein transport across the ER membrane.



K28 Affects DNA Synthesis, Cell-Cycle Progression, and Induces Apoptosis

Although the cytotoxic α-component of K28 (10.5 kDa) can enter the nucleus by passive diffusion, extension of α by a classical nuclear localization sequence (NLS) significantly enhances its *in vivo* toxicity due to faster and more efficient nuclear import mediated by α/β importins of the host. Within the nucleus, α interacts with host proteins of essential function in eukaryotic cell cycle control and initiation of DNA synthesis. Thus, as the virus toxin targets evolutionary highly conserved proteins with basic and central function, toxin resistance mechanisms based on mutations in essential chromosomal host genes hardly

occur *in vivo*, indicating that the toxin has developed a very efficient strategy to penetrate and kill its target cell. Most interestingly, while high toxin concentrations (10 pmol or higher) cause necrotic cell killing via cell-cycle arrest and inhibition of DNA synthesis, treatment with low doses of viral killer toxins (<1 pmol) results in an apoptotic host-cell response triggered by the accumulation of reactive oxygen species, ROS (**Figure 5**). Since toxin concentration is usually low in the natural environment of a killer yeast, toxin-induced apoptosis is probably an important prerequisite for efficient cell killing. Furthermore, since apoptosis is also important in the pathogenesis of virus infections in mammals, it is not surprising that toxin-encoding yeast killer viruses (as has been shown for ScV-M1 and ScV-M2) can also induce a programmed suicide pathway in noninfected yeast. Although viral killer toxins were shown to be primarily responsible for this phenomenon, yeast killer viruses are not solely responsible for triggering a cell death pathway in yeast.

Lethality of Membrane Damaging Viral Killer Toxins

Yeast viral killer toxins kill sensitive cells in a receptor-mediated fashion by interacting with receptors at the level of the cell wall and the cytoplasmic membrane (**Figure 5**). The initial step involves rapid toxin binding to a primary receptor R1 which is localized within the mannoprotein or β-1,6-glucan fraction of the cell wall. In the second step the toxin translocates to the plasma membrane and interacts with a secondary receptor R2 (**Figure 5**). To date, only the membrane receptor for the K1 virus toxin has been identified: Kre1p, an O-glycosylated cell surface protein initially GPI-anchored to the plasma membrane and involved in β-1,6-glucan biosynthesis and K1 cell wall receptor assembly. Once bound to the plasma membrane, ionophoric virus toxins (such as K1 and zygocin) disrupt cytoplasmic membrane function by forming cation-selective ion channels, while K28 enters the cell and acts in the nucleus: DNA

Toxin	Target	Receptor R1	Receptor R2
K1 (α/β) (19 kDa)	Plasma membrane	Glucan	Kre1p
K28 (α/β) (21 kDa)	DNA, cell cycle	Mannoprotein	Unknown
Zygocin (10 kDa)	Plasma membrane	Mannoprotein	Unknown

Figure 5 Receptor-mediated toxicity of the viral killer toxins K1, zygocin, and K28. Killing of a sensitive yeast is envisaged in a two-step process involving initial toxin binding to receptors within the cell wall (R1) and the cytoplasmic membrane (R2). After interaction with the plasma membrane, ionophoric toxins such as K1 and zygocin disrupt cytoplasmic membrane function, while K28 enters the cell by endocytosis and diffuses into the nucleus to cause cell death (note that the cell surface receptors R1 and R2 are different in all three toxins; see also table inset). At high toxin doses (>10 pmol) sensitive cells arrest in the cell cycle with pre-replicated DNA (1n; left panel), while cells treated with K28 in low concentrations (<1 pmol) respond with apoptosis as shown by typical apoptotic markers such as chromosomal DNA fragmentation (TUNEL-positive cells), accumulation of reactive oxygen species (ROS), and phosphatidylserin exposure at the external surface of the plasma membrane detected by annexin-V staining (right panel).

synthesis is rapidly inhibited and cells arrest at the G1/S boundary of the cell cycle (**Figure 5**).

Ion channel formation in yeast membranes induced by the K1 virus toxin was initially reported using patch-clamping techniques as a result from direct toxin action. However, this observation is inconsistent with the complete resistance seen in immune yeast cell spheroplasts, and so far receptor-independent channels have not been observed, neither in yeast membranes nor in *Xenopus laevis* oocytes. Similar to K1 (and probably K2 as well), zygocin represents a membrane-damaging virus toxin which is produced and secreted by ZbV-M-infected killer strains of the osmotolerant spoilage yeast *Z. bailii*. Zygocin itself is a monomeric, nonglycosylated protein toxin with an unusual broad killing spectrum, being equally active against phytopathogenic as well as human pathogenic yeasts including *Candida albicans*, *C. glabrata*, *C. tropicalis*, and *Sporothrix schenkii*. Since even filamentous fungi such as *Fusarium oxysporum* and *Colletotrichum graminicola* are effectively killed by the toxin, zygocin represents a virus toxin with significant antimycotic potential. Similar to K1 but significantly more efficient, zygocin disrupts plasma membrane integrity and causes rapid cell killing. Its ionophoric mode of action has been reinforced by *in silico* sequence analysis, identifying a stretch of potential α-helical conformation that forms an amphipathic structure characteristic for membrane-disturbing antimicrobial peptides such as alamethicin, melittin, and dermaseptin. In addition, this feature is accompanied by a transmembrane helix at the C-terminus of zygocin which is predicted to favor a membrane permeabilizing potential, not by activating native ion channels but rather by establishing pores by itself after toxin oligomerization. It is therefore assumed that the hydrophobic part in zygocins' amphipathic α-helix is responsible for toxin binding to the target cell. The postulated model of zygocin action resembles that of human α-defensins. In analogy to alamethicin, toxicity of zygocin is probably mediated by incorporation of its transmembrane helix into the plasma membrane, a process solely driven by the natural transmembrane potential of the energized yeast and fungal plasma membrane. Thus, zygocins' mode of action portrays the lethal mechanism of antimicrobial peptides that are produced by virtually all higher eukaryotes. Mechanisms of resistance against antimicrobial peptides are rare and often limited to changes in the composition of the cytoplasmic membrane. In major contrast to mammalian cells, the outer leaflet of yeast and fungal membranes is enriched in negatively charged lipids. Due to the cationic net charge of antimicrobial peptides (including zygocin), an affinity to these lipids facilitates toxin adsorption to the target membrane. Consistent with that, deletion of chromosomal genes whose gene products affect plasma membrane lipid composition (such as *PDR16* and *PDR17*) causes a dramatic decrease in zygocin sensitivity because toxin binding to the plasma membrane is largely prevented in the genetic background of a yeast *pdr16/17* mutant. In contrast to K1, a zygocin-specific membrane receptor is not required for its *in vivo* toxicity as the physicochemical properties of zygocin allow efficient plasma membrane interaction independent of any membrane receptor or docking protein.

Self-Protection in Killer Virus-Infected Yeast – Toxin Immunity

For many decades it was unknown how a killer virus-infected yeast protects itself against its own secreted toxin. In killer yeast, functional immunity is essential for survival since the toxins often target and inhibit central eukaryotic cell functions. This is in major contrast to bacterial toxins such as cholera toxin and Shiga toxins which selectively kill eukaryotes, thus making immunity dispensable in a prokaryotic host. Recently, the mechanism of protecting immunity against the K28 virus toxin has been elucidated. It is now known that immune cells take up external toxin (either produced by itself or by other K28 killers) and translocate it back to the cytosol where the reinternalized α/β toxin rapidly forms a complex with the pptox precursor that has not yet been imported into the ER. Within this complex, the K28 heterodimer is selectively ubiquitinated and proteasomally degraded while the pptox moiety of the complex is in part released to be either imported into the ER (to give active virus toxin) or to complex a newly internalized K28 heterodimer. In this process, the amount of cytosolic ubiquitin is critical for immunity and overexpression of mutant ubiquitin (blocked in polyubiquitin chain formation) results in a significant decrease in toxin secretion and a suicidal phenotype based on nonfunctional immunity. Alternatively, decreasing cytosolic ubiquitin causes an increase in toxin secretion, while immunity is not impaired as sufficient pptox is available for K28 complex formation. This simple and highly efficient mechanism ensures that a toxin-producing killer yeast is fully protected against the lethal action of its own toxin. In contrast to K28 immunity, the precise mechanism(s) of self-protection against the ionophoric virus toxins K1 and zygocin is still obscure and remains largely unknown.

Viral Membranes

J Lenard, University of Medicine and Dentistry of New Jersey (UMDNJ), Piscataway, NJ, USA

Introduction

Viruses of many kinds possess lipids as integral components of their structure. Lipid-containing, or enveloped, viruses include: *Baculo-*, *Bunya-*, *Corona-*, *Filo-*, *Herpes-*, *Lenti-*, *Orthomyxo-*, *Paramyxo-*, *Pox-*, *Retro-*, *Rhabdo-*, and *Togaviridae*. Despite the great diversity of these viruses in regard to structure, replicative strategy, host range and pathogenicity, the function of the lipids in each case is the same – to form a membrane surrounding the encapsidated viral RNA or DNA genome. The lipids of the viral envelope form a continuous bilayer that functions as a permeability barrier protecting the viral nucleocapsid from the external milieu. Embedded in this bilayer are numerous copies of a limited number of virally encoded transmembrane proteins (often just one or two) that are required for virus entry into a potential host cell. These proteins mediate two essential functions: attachment of the virion to the cell surface; and fusion of the viral envelope with a cell membrane, resulting in accession of the viral nucleocapsid containing the genome to the cellular cytoplasm.

The membrane is acquired during viral assembly within an infected cell. This generally occurs by the budding of the previously assembled viral nucleocapsid through a cell membrane, incorporating host cell lipids and viral membrane proteins, but excluding virtually all cell membrane proteins. The particular cell membrane through which viral budding occurs is characteristic for each virus. Many viruses bud through the plasma membrane, but bunyaviruses bud through the Golgi apparatus, coronaviruses chiefly through the endoplasmic reticulum, and herpesviruses through the nuclear membrane. Poxviruses, which are among the largest and most complex animal viruses, are unique in acquiring two discrete membranes through a series of interactions with different cellular organelles, in a process that is not well understood.

Viral membranes have been extensively studied for many years, and for many reasons. The budded viral envelopes themselves represent isolated, readily purifiable subdomains of discrete cellular membrane bilayers. The envelope proteins that mediate entry of viruses into infectible cells are regarded as prototypes of membrane fusion machines. The initial binding of virions to potential host cells is mediated by prototypical ligand–receptor interactions in which viral proteins (ligands) bind to cell surface proteins (receptors). These properties of viral envelopes represent potential targets for antiviral therapy; they also provide models for important cellular phenomena.

Viral Bilayers

For many non-pathogenic viruses that can be readily purified in sufficient quantities in the laboratory, the bilayer arrangement of lipids in the viral envelope has been directly demonstrated using physical methods. It is assumed that the lipids in all viral envelopes are similarly arranged in a bilayer, based on those observations, and on the fact that the host cell membranes from which the viruses bud all contain bilayers, and also because it is the only physically reasonable arrangement of lipids that could supply the required protection from environmental stresses. Intact virions are impermeant to proteases and other enzymes.

Indeed, virions can swell and shrink in response to changes in osmolarity, showing that viral envelopes are impermeant to small molecules and ions as well as large proteins, and thus must consist of intact bilayers that completely surround the encapsidated viral genome.

The lipid composition of various viruses grown under different conditions, and in different cell types, has been studied in detail. These have shown that wide variations in lipid composition are tolerated in many viruses; they have provided no evidence that any substantial fraction of envelope lipids is bound to viral envelope proteins specifically, or exists in a nonbilayer conformation.

Recent studies have shown that many viruses bud from specialized regions of the plasma membrane known as 'rafts'. Rafts are regions of the plasma membrane characterized by high concentrations of sphingolipids (sphingomyelin and sphingoglycolipids) and cholesterol. These components participate in the formation of separate, partially miscible phases, distinguishable from the more fluid phase(s) which are relatively enriched in unsaturated phospholipids. Raft and non-raft phases co-exist as contiguous bilayers, but diffusion is relatively restricted within raft phases, and exchange of molecules between phases occurs more slowly than diffusion within a single phase. Although the existence of local heterogeneity in lipid and protein structure has been demonstrated in cell membranes using a variety of physical and detergent extraction techniques, a precise definition of rafts has not been achieved. There is little agreement regarding their size, or whether they are nucleated by lipids or by proteins. Despite these uncertainties, certain membrane constituents are clearly concentrated in specialized regions rich in sphingolipids and cholesterol, and these have been identified as the sites of important cellular signaling and transport functions, and of assembly and budding for many enveloped viruses. Detailed lipid analyses of purified budded virions have confirmed their origin in rafts, and have in turn helped to define the lipid composition of virus-associated rafts.

Viral Membrane Proteins

The proteins of viral membranes, like those of other membranes, may be classified as either integral or peripheral. Integral proteins are those that cross the membrane bilayer at least once, and thus cannot be solubilized without disrupting the bilayer, that is, without using detergents. Peripheral proteins are also membrane associated, but they do not cross the membrane and they can be removed from it by treatment with aqueous salts, high pH or chaotropic agents, which leave intact the hydrophobic interactions that stabilize the bilayer.

Most integral membrane proteins of enveloped viruses span the bilayer only once, although exceptions exist. Each transmembrane (anchoring) domain is a sequence of 18–27 predominantly hydrophobic amino acid residues. Because transmembrane sequences are inherently insoluble in water, integral membrane proteins require detergents for extraction from the bilayer and solubilization. When detergents and lipids are both removed from purified viral proteins, they tend to aggregate into rosettes, forming a kind of protein micelle, with the transmembrane sequences clustered together at their centers in order to maximize hydrophobic interactions and minimize contact with water. Purified viral membrane proteins can be reinserted into lipid bilayers of defined composition by mixing the detergent-solubilized protein with lipids, then removing the detergent by dialysis. These reconstituted viral membranes ('virosomes') often possess the native receptor binding and fusion activities.

The functions of the major integral viral membrane proteins are: first, to attach the virus to the uninfected host cell; and second, to effect penetration of the genome into the host cell cytoplasm through membrane fusion of the viral envelope with a host cell membrane. As much as 90% of each viral receptor binding/fusion protein is external to the viral membrane and thus accessible to removal and/or degradation by added proteases. Viral membrane proteins are often morphologically identifiable in electron micrographs as 'spikes' on the outer surface of membrane particles. Under favorable conditions, nearly the entire external domain may be rendered soluble and recovered intact and correctly folded after proteolytic removal from the virion, facilitating crystallization and structural analysis. These domains possess oligosaccharide side chains identical to those of cellular integral proteins in structure and attachment sites, and often possess disulfide bonds as well, reflecting the viral proteins' normal procession through the cell's endoplasmic reticulum–Golgi system (**Figure 3**).

While these proteins constitute the major fraction (>95%) of viral integral membrane proteins, there is an additional class of small integral proteins that oligomerize within the bilayer to form channels that facilitate the transport of ions or small molecules. These proteins have been called 'viroporins'. They include the M2 protein of influenza, the 6K protein of alphaviruses, and Vpu of HIV-1. They are thought to function in various ways to facilitate the assembly and release of new viral particles from the infected cell.

Peripheral membrane proteins are attached to the viral membrane by a combination of hydrophobic and electrostatic interactions. They may penetrate the bilayer to some extent, but they do not cross it as integral proteins do. Viral peripheral membrane proteins include M1 of influenza, M of paramyxoviruses, and MA of retroviruses. All enveloped viruses except the togaviruses encode an M-like peripheral protein that functions to bring together the envelope and nucleocapsid components during viral assembly.

Cellular Virus Receptors: Virus Membranes as Ligands

The first step in infection, attachment of the virus to the outer surface of the host cell, is performed by specific membrane proteins of enveloped viruses. One or more unique cellular 'receptors' are recognized by each species or strain of virus. The presence of a specific cellular receptor is often the major factor determining the susceptibility of a particular species to infection; it also determines the infectibility of different tissues or cells within infected individuals.

Different viruses may bind to any of a large number of different cell surface proteins, carbohydrates, or lipids. Binding serves several purposes. Most generally, it attaches the virus to the uninfected cell, maintaining proximity, and increasing effective viral concentration on the cell surface. More specifically, interaction of viral spikes with specific cell surface proteins may initiate conformational changes that activate the viral proteins for fusion. Binding to certain cell surface proteins may also promote endocytosis of the virus, by any of several cellular pathways. Endocytosis introduces the viral envelope into the lower pH of the endosome, which is required for activation of some viral fusion proteins. Activation of certain cell surface receptors by virus binding may also initiate specific signaling cascades within the cell, which may be useful to the virus during subsequent steps of infection.

Each enveloped virus exhibits unique binding specificities of its membrane proteins with particular cell surface features, resulting in a unique combination of these effects. For example, the HIV-1 recognition protein gp120 exhibits a near total specificity for binding to the CD4 receptor on immune cells. Further activation of the virus' fusion protein gp40 occurs by interaction with a co-receptor, either the chemokine receptor CCR5 or CXCR4. In contrast, orthomyxo- and many paramyxoviruses have much broader specificity. Their recognition proteins (HA or HN, respectively) bind to sialic acid residues attached to various cell surface proteins or lipids. Different strains show preference for sialic acid in different covalent linkages. Rhabdoviruses such as vesicular stomatitis or rabies virus are still less specific, binding indiscriminately to negative charge clusters, whether created by lipids, proteins, oligosaccharides, or surface-bound polyanions. This nonspecific binding property helps to account for the broad host range of these viruses, although some have also been reported to bind specifically to acetylcholine receptors, which may explain their neurotropism.

Viral Fusion

Fusion of the viral envelope with a cell membrane is facilitated by integral viral membrane proteins. The best studied viruses (HIV-1, orthomyxo-, paramyxo-, retro-, toga-, and rhabdoviruses) each possess a single fusogenic glycoprotein, but herpes- and poxviruses may possess several that work together. Virosomes consisting only of a purified viral fusion protein reconstituted into a lipid bilayer vesicle fuse readily with protein-free lipid bilayers, suggesting that the fusion proteins can act on host cell lipids and do not require participation by host cell proteins.

Because of their ready availability and ease of purification, viral fusion proteins have served as prototypes for understanding biological fusion reactions. Several general principles have emerged, which have been found to apply to at least one major class of cellular fusion reactions (those mediated by proteins called SNAREs) as well as all characterized viral fusions.

First, both viral and cellular fusion proteins act directly on the lipid bilayer to facilitate rearrangements identical to those that occur during protein-free lipid bilayer fusion. Fusion is thought to occur through a series of steps, constituting the so-called 'stalk–pore' pathway (**Figure 1**). The two closely apposed bilayers (**Figure 1**(**a**)) dimple

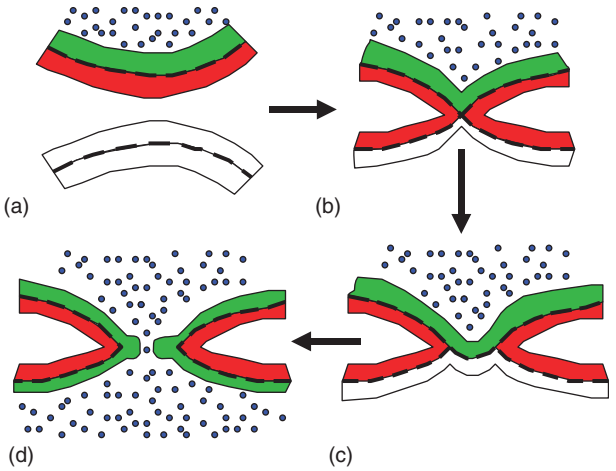

Figure 1 The stalk–pore mechanism of membrane bilayer fusion. (a) Initial pre-fusion state. The two leaflets of the cell membrane bilayer are colored green and red. The cytoplasm is indicated by blue dots. The viral membrane is colorless. (b) The stalk structure. In this state, continuity is established between the outer leaflets of the two membrane bilayers, allowing lipid mixing. (c) The fusion diaphragm constitutes a single bilayer separating the two aqueous compartments, comprising the inner leaflets of the cellular and viral membrane bilayers. The outer leaflets have already fused, and their lipids have mixed. (d) The fusion pore arises from rearrangement of the limited-area fusion diaphragm, perhaps facilitated by fusion proteins. Expansion of the fusion pore allows complete mixing of aqueous compartments and completes fusion. Fusion can occur even between protein-free lipid bilayers under certain conditions, but fusion proteins increase efficiency, probably by acting at each step in this pathway. Reproduced from Chernomordik LVand Kozlov MM (2005) Membrane hemifusion: Crossing a charm in two leaps. *Cell* 123: 375–382.

towards each other to form the 'stalk' (**Figure 1(b)**). This thins to form a 'hemifusion diaphragm' (**Figure 1(c)**), which now separates the two aqueous compartments by a single membrane bilayer in place of the two that separated them in the pre-fusion state. The hemifusion bilayer consists of the inner leaflets of the two original bilayers, the outer leaflets having already fused with consequent mixing of their lipid components. The hemifusion diaphragm can then rearrange to form a 'fusion pore' (**Figure 1(d)**), which must stabilize and widen to allow aqueous mixing, and thus complete the fusion reaction.

Precisely how viral membrane proteins promote fusion via the stalk–pore mechanism remains a subject of active research. Several properties of viral fusion proteins are known to be essential for activity, however. All viral and cellular fusion proteins are oligomeric, usually trimeric for virus fusion proteins. In most cases, several (probably 5–7) trimers must act cooperatively in order to complete the fusion reaction. One attractive idea is that the several fusion protein trimers encircle a limited area of bilayer, into which the fusion proteins can then transfer the energy released by their ensuing conformational transitions (**Figure 2**) in order to effect the lipid rearrangements required for fusion. Viral fusion proteins might potentiate any or all of the fusion steps: initial stalk formation, hemifusion diaphragm formation from the stalk, fusion pore formation from the hemifusion diaphragm, expansion of the initial fusion pore to complete fusion.

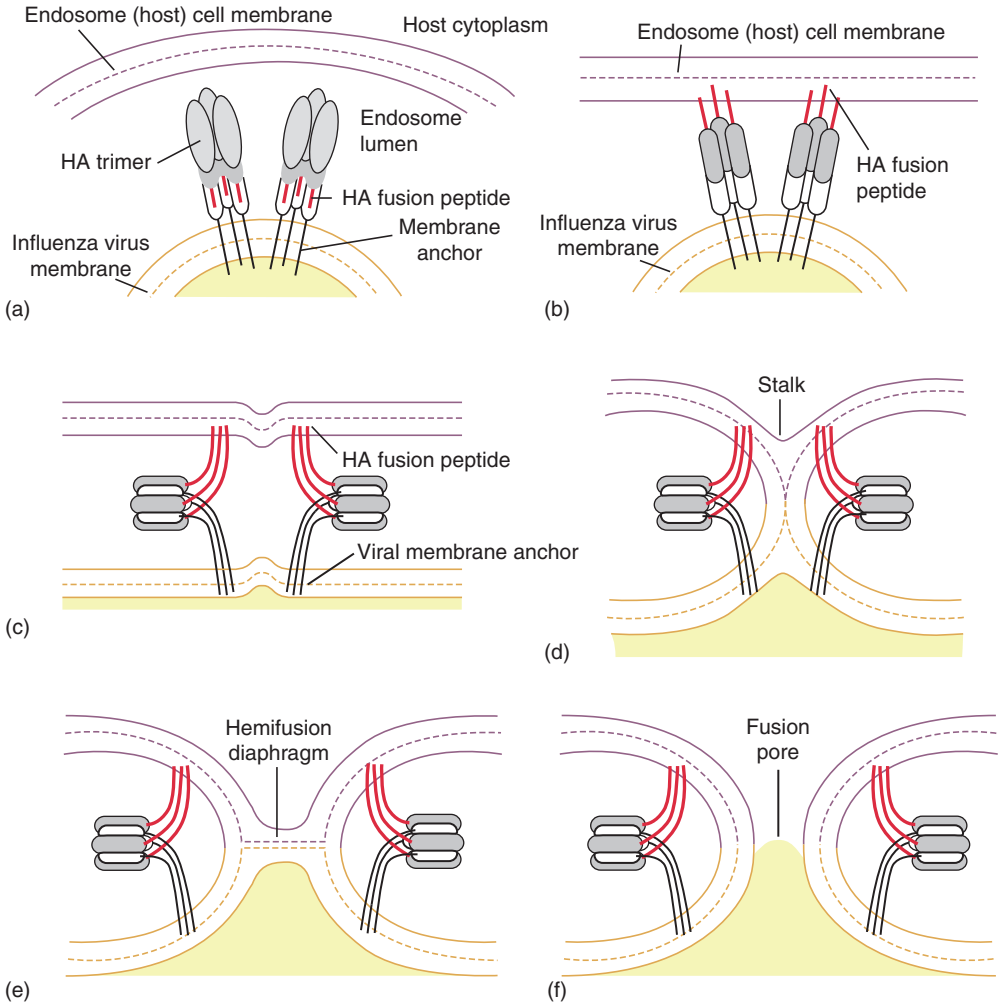

Figure 2 Proposed stalk–pore mechanism for membrane fusion mediated by a class I virus fusion protein, influenza hemagglutinin, HA. (a) The influenza virus has been internalized into the host cell endosome by receptor-mediated endocytosis (not shown). (b) Acidification of the endosome causes a conformational change in HA, which causes the fusion peptide (red) to become exposed; it subsequently inserts into the endosomal membrane. (c) Further refolding and clustering of HA trimers leads to bending of the two membranes toward each other. The resulting stalk (d) rearranges into the hemifusion diaphragm (e), where the virus interior is separated from the cytoplasm by a single bilayer, composed of the internal leaflets of the original membranes. This eventually rearranges, resulting in the formation of the fusion pore (f), which initially flickers and then dilates to complete the fusion reaction (not shown). Intra-leaflet lipid mixing, illustrated in **Figure 1**, is not shown. From Cross KJ, Burleigh LM, and Steinhauer DA (2001) Mechanism of cell entry by influenza virus. *Expert Reviews in Molecular Medicine* 6: 1–18, Cambridge University Press.

Within these general principles two distinct classes of viral fusion proteins have been recognized, possessing radically different architecture. Type I viruses include orthomyxo-, paramyxo-, retro-, and coronaviruses. Type II viruses include toga- and flaviviruses. Despite their different structures, these two classes of proteins facilitate the same lipid modifications during fusion.

All virus fusion proteins must remain inactive during biosynthesis and assembly so as to prevent premature, indiscriminate, counterproductive fusion within the infected cell. Both type I and type II fusion proteins are activated by a two-step process potentiated by interactions with a host cell. The inactive type I precursor protein is first cleaved at a specific site by limited proteolysis during assembly, generating a metastable, active form (**Figure 2**(**a**)). This then undergoes a conformational change mediated either by interaction with a specific cellular co-receptor (HIV-1), or by interaction with viral recognition proteins (paramyxoviruses) or by the low pH inside an endosome (orthomyxoviruses). Type II viral fusion proteins acquire their active conformation by an incompletely understood rearrangement of viral envelope proteins to form fusion protein trimers followed by interactions with specific lipids, notably cholesterol.

Activated fusion proteins of either type possess the following three structural features, which are required for complete fusion (**Figure 2**):

1. *Transmembrane domain.* This is the helical hydrophobic sequence (around 20 residues) that defines the fusion protein as an integral protein, and fixes it irreversibly in the viral bilayer. The transmembrane domain is inserted into the membrane bilayer during synthesis on membrane-bound ribosomes and appears not to rearrange during subsequent processing, activation or fusion. Type I and type II fusion proteins possess similar transmembrane domains. Not all transmembrane domains can participate in fusion reactions; a certain amount of conformational flexibility is required.

The transmembrane domain is required to complete the fusion reaction. Constructs in which the external, fusogenic domain of the influenza HA protein was attached only to the outer leaflet of the viral bilayer by a covalent bond with a lipid were capable of inducing hemifusion only, but were unable to complete the reaction.

2. *Fusion peptide.* This is a second relatively hydrophobic sequence that inserts into the cell membrane bilayer, and thus serves to bind the virus and cell membranes together. Exposure of the fusion peptide, enabling it to penetrate the target cell membrane, is an essential aspect of fusion protein activation, and requires a conformational change from a precursor form (**Figure 2**(**b**)). In type I proteins, this results from proteolytic activation; the influenza fusion peptides, for example, comprise the newly created N termini. Type II fusion peptides are located in a protruding loop of the protein structure, which is exposed by a poorly understood interaction with lipids, notably cholesterol. As with the transmembrane domain, a certain amount of conformational flexibility is required in the fusion peptide.

3. *A rigid, oligomeric rod-like structure connecting the fusion peptide with the transmembrane domain.* This consists of a helical coiled-coil in type I proteins (**Figure 2**(**b**)), and an arrangement of β-sheet domains in type II proteins. Once the fusion peptide has inserted into the target membrane, fusion is completed by the rearrangement of this metastable structure to its lowest free energy form (**Figures 2**(**d**)–**2**(**e**)). In order to assume this form, the rigid oligomer folds back upon itself, forming a 'hairpin' (**Figures 2**(**d**)–**2**(**e**)), thus dragging the cell membrane, tethered by the fusion peptide, toward the viral membrane, tethered by the transmembrane domain. The free energy released by this rearrangement is transferred to the lipid bilayers, providing the energy necessary to complete the fusion reaction. In the final fused product, the fusion peptide and the transmembrane domain are adjacent to each other in the same membrane, held in proximity by the fully stable, rigid hairpin (**Figure 2**(**f**)).

Membrane Synthesis and Viral Assembly

Viruses generally use the housekeeping mechanisms already operating in the infected cell in order to make maximal use of their limited genomes. Hence, viral membrane protein synthesis is carried out on host cell membrane-bound ribosomes, which inserts them into the endoplasmic reticulum membrane in the correct orientation (**Figure 3**). There they are glycosylated by the host cell machinery and assembled into appropriate oligomers, as directed by their own primary amino acid sequence. Most viral glycoproteins are then passed on to the Golgi by cellular mechanisms, where they are further glycosylated by host cell enzymes. For this reason, the envelope proteins of vesicular stomatitis virus (VSV), influenza, and a few other enveloped viruses have provided valuable tools to study the glycosylation and transport of membrane proteins through the cellular endoplasmic reticulum–Golgi–plasma membrane system. Because host cell protein synthesis is often inhibited by infection with these viruses (by a variety of cytopathic mechanisms), large amounts of a single viral membrane protein are produced and correctly processed in infected cells, without competition by cellular proteins.

Likewise, viral proteins are targeted to specific cellular locations by cellular processes. The viral proteins display the same amino acid sequence 'addresses' as host cell proteins, which are recognized by the host cell glycosylation and transport machinery. For example, the single VSV glycoprotein, named G, is glycosylated in the endoplasmic

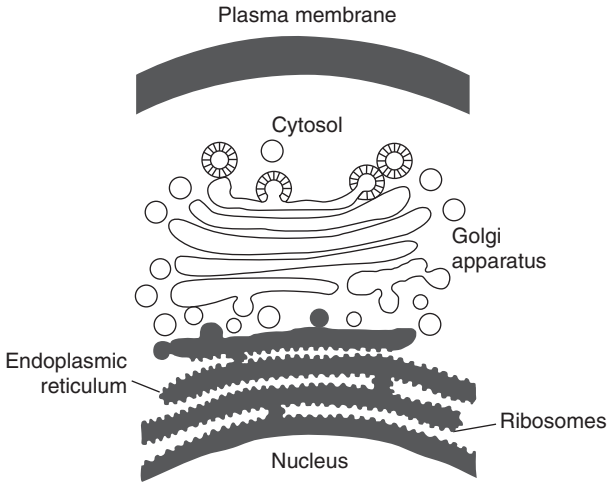

Figure 3 The endoplasmic reticulum–Golgi–plasma membrane system of a cell. All viral and cellular integral membrane proteins are synthesized by ribosomes bound to the endoplasmic reticulum membrane. Proteins destined for the plasma membrane are transported first to the proximal region of the Golgi (the *cis* face), then sequentially through the Golgi cisternae, to the *trans* face and out to the plasma membrane. In polarized cells, targeting to the apical or basolateral surface of the cell occurs from the *trans* face of the Golgi. Assembly and budding of different enveloped viruses occurs at characteristic points within this membrane system.

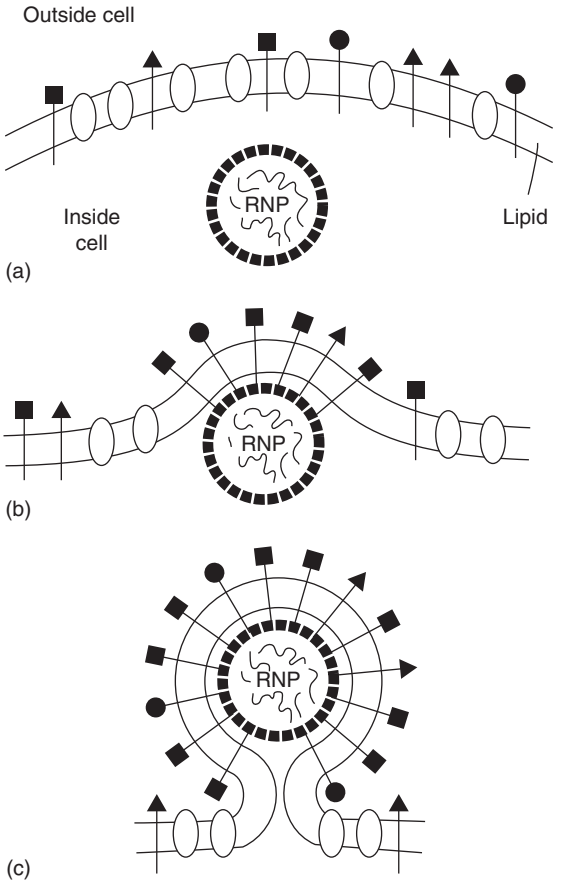

Figure 4 One kind of virus budding. Viral glycoproteins, inserted into the cellular membrane at the endoplasmic reticulum and processed through the Golgi to the plasma membrane (see **Figure 3**), associate with the assembled viral nucleocapsid. The direct association pictured here is characteristic of togaviruses. For other viruses, possessing helical nucleocapsids, the association is mediated by a peripheral membrane protein. Cellular membrane proteins are excluded from the envelope of the mature virion. This may occur during assembly, as pictures, or by prior formation of a viral membrane patch (or raft), before the nucleocapsid arrives at the membrane.

reticulum, the oligosaccharide is modified in the Golgi, and the mature protein is targeted to the basolateral plasma membrane of polarized cells after entry into the late Golgi. The influenza HA protein, on the other hand, is glycosylated and delivered to the apical plasma membrane of the same polarized cells after passage through the intracellular membrane system. The retention of coronavirus glycoproteins by the endoplasmic reticulum, and of bunyavirus glycoproteins by the Golgi, reflects the operation of the same cellular mechanisms that retain resident cellular proteins in these organelles. The localization of viral membrane proteins in turn, determines the location of viral assembly and budding.

The budding process consists of the wrapping of a viral glycoprotein-enriched piece of membrane around the previously assembled nucleocapsid, which contains the viral genome (**Figure 4**). Remarkably, the completed viral envelope contains viral proteins and host cell lipids, with host cell membrane proteins being almost completely excluded. There is much less discrimination, however, between different viral proteins than between viral and cellular proteins, since viral envelope proteins of one kind can assemble with nucleocapsids of another, resulting in the formation of pseudotype virions. Pseudotypes have proven useful in redirecting specific viral genomes to alternate host cells since membrane attachment proteins are major determinants of host cell specificity (see above). It has been suggested that the discrimination between viral and cellular membrane proteins may arise from the exclusion of cellular proteins from virus-associated raft-like lipid phases.

Different viruses have been described, that bud at every stage in the endoplasmic reticulum–Golgi–plasma membrane pathway (**Figure 3**). While paramyxo-, orthomyxo-, rhabdo-, and togaviruses (and many others) generally bud from the plasma membrane, they have also been shown to bud intracellularly under certain conditions. Some retroviruses assemble at the plasma membrane, while others do not; this has provided a classical basis for distinguishing between different types of retroviruses. Other viruses normally bud intracellularly, from the endoplasmic reticulum or Golgi apparatus, for example, coronaviruses and bunyaviruses respectively, but these have also

been observed to bud further down the pathway. In these cases, the nucleocapsid assembles on the cytoplasmic face of the membrane, and then buds into the intracellular organelle. The newly formed virion may then be secreted out of the cell through the normal secretory pathway, although this does not always occur efficiently.

In all enveloped viruses except togaviruses, budding is mediated by a peripheral membrane protein, usually called M or MA, which links the glycoprotein-containing patch of lipids with the viral nucleocapsid, containing the viral genome. The M proteins interact specifically with nucleocapsids of their own viral species, but they do not always interact specifically with the corresponding viral glycoproteins. Instead, they may concentrate on the cytoplasmic side of the raft-like lipid phases that accumulate various viral glycoproteins. This could provide the structural basis for the formation of pseudotype virions, and might explain why many viruses contain widely varying ratios of glycoproteins to M or nucleocapsid proteins.

In contrast, togaviruses, which lack any M protein, possess an icosahedral nucleocapsid, which interacts directly with the cytoplasmic domain of the viral membrane protein. Completed virions contain an equal number of nucleocapsid and membrane protein molecules. Both are in a similar geometric arrangement, mediated by specific protein–protein interactions between them.

As described above, the lipids of the viral membrane are taken from the host cell membrane during budding. No new lipids are specifically synthesized in response to viral infection. Alterations in cellular lipid metabolism have been reported to result from some viral infections in cultured cells, but these are probably secondary to other cytopathic effects; there is no indication that they play an important role in the progress of infection.

Viral Pathogenesis

N Nathanson, University of Pennsylvania, Philadelphia, PA, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Viral pathogenesis deals with the interaction between a virus and its host. Included within the scope of pathogenesis are the stepwise progression of infection from virus entry through dissemination to shedding, the defensive responses of the host, and the mechanisms of virus clearance or persistence. Pathogenesis also encompasses the disease processes that result from infection, variations in viral pathogenicity, and the genetic basis of host resistance to infection or disease. A subject this broad cannot be treated in a single entry, and this article focuses on the dissemination of viruses and their pathogenicity.

Sequential Steps in Viral Infection

One of the cardinal differences between viral infection of a simple cell culture and infection of an animal host is the structural complexity of the multicellular organism. The virus must overcome a number of barriers to accomplish the stepwise infection of the host, beginning with entry,

followed by dissemination, localization in a few target tissues, shedding, and transmission to other hosts.

Entry

Some viruses (such as papillomaviruses, poxviruses, and herpes simplex viruses) will replicate in cells of the skin or mucous membranes. Following infection of skin, viruses may spread further by passage of intact virions or virus-infected macrophages and dendritic cells to the regional lymph nodes. A considerable number of viruses cause sexually transmitted infection, which is usually acquired by either by penetration through breaks in the skin or by direct invasion of the superficial epithelium of the mucous membranes. Contaminated blood, semen, or secretions may introduce hepatitis B virus directly into the circulation via breaks in skin and membranes, while human immunodeficiency virus (HIV) may be trapped on the surface of dendritic cells (Langerhans cells) in the epidermis and then transported to draining lymph nodes. Although the skin is a formidable barrier, mechanical injection that breaches the barrier is a 'natural' route of entry for many viruses. More than 500 individual arboviruses are maintained in nature by a cycle that involves a vector and a vertebrate host. When the infected vector takes a blood meal, virus contained in the salivary gland is injected. Also, virus may be transmitted accidentally by contaminated needles, injection of a virus-contaminated therapeutic, transfusion with virus-contaminated blood or blood products, or tattooing.

The oropharynx and gastrointestinal tract are important portals of entry for many viruses, and enteric viruses may invade the host at a variety of sites from the oral cavity to the colon. Some viruses produce localized infections that remain confined to the gastrointestinal tract whereas others disseminate to produce systemic infection. Most enteric viruses, such as rotaviruses, infect the epithelium of the small or large intestine, but some enteroviruses, such as poliovirus, replicate in the lymphoid tissue of the gut and nasopharynx. There are numerous barriers to infection via the enteric route. First, much of the ingested inoculum will remain trapped in the luminal contents and never reach the wall of the gut. Second, the lumen constitutes a hostile environment because of the acidity of the stomach, the alkalinity of the small intestine, the digestive enzymes found in saliva and pancreatic secretions, and the lipolytic action of bile. Third, the mucus that lines the intestinal epithelium presents a physical barrier protecting the intestinal surface. Fourth, phagocytic scavenger cells and secreted antibodies in the lumen can reduce the titer of infectious virus. Viruses that are successful in using the enteric portal tend to be resistant to acid pH, proteolytic attack, and bile, and some may actually exploit the hostile environment to enhance their infectivity. The importance of anal intercourse as a risk factor for hepatitis B and HIV infection has led to the recognition that some viruses can gain entry through the lower gastrointestinal tract, but the exact mechanism of HIV infection through the anocolonic portal remains to be determined.

Respiratory infection may be initiated either by virus contained in aerosols that are inhaled by the recipient host, or by virus that is contained in nasopharyngeal fluids and is transmitted by hand-to-hand contact. Aerosolized droplets are deposited at different levels in the respiratory tract depending upon their size: those over 10 μm diameter are deposited in the nose, those 5–10 μm in the airways, and those <5 μm in the alveoli. Once deposited, the virus must bypass several effective barriers, including phagocytic cells in the respiratory lumen, a covering layer of mucus, and ciliated epithelial cells that clear the respiratory tree of foreign particles. The temperature of the respiratory tract varies from 33 °C in the nasal passages to 37 °C (core body temperature) in the alveoli. Viruses (such as rhinoviruses) that can replicate well at 33 °C but not at 37 °C are limited to the upper respiratory tract and, conversely, viruses that replicate well at 37 °C but not at 33 °C (such as influenza virus) mainly infect the lower respiratory tract. Most respiratory viruses initiate infection by replicating in epithelial cells lining the alveoli or the respiratory tree, but some viruses will also replicate in phagocytic cells located either in the respiratory lumen or in subepithelial tissues.

Spread

Once infection is established at the site of entry, most viruses will spread locally by cell-to-cell transmission of infection. Some viruses remain localized near their site of entry while others disseminate widely. Viruses that are released only at the apical surface of infected cells tend to remain localized, while those that are released at the basal surface tend to disseminate. Usually, the first step in dissemination of the infection is the transport of virus via the efferent lymphatic drainage from the initial site of infection to the regional lymph nodes, either as free virions or in virus-infected phagocytic cells.

The single most important route of dissemination is the circulation, which can potentially carry viruses to any site in the body. There are several sources of viremia. Virus may enter with the efferent lymphatic flow, or may be shed from infected endothelial cells or circulating mononuclear leukocytes. Viruses can circulate either free in the plasma phase of the blood ('plasma' viremia) or associated with formed elements ('cell-associated' viremia), and these two types of viremia have quite different characteristics. An 'active' viremia is caused by the active replication of virus in the host, which occurs after a lag

period required for tissue replication and shedding into the circulation. Termination of viremia is often quite abrupt and coincides with the appearance of neutralizing antibody in the serum.

Plasma viremia reflects a dynamic process in which virus continually enters the circulation and is removed. The rate of turnover of virus within the plasma compartment is best expressed as transit time, the average duration of a virion in the blood compartment. Typically, transit times range from 5 to 60 min and tend to decrease as the size of the virions increases. Circulating viruses are removed by the phagocytic cells of the reticuloendothelial system, principally in the liver (Kupffer cells), and to a lesser extent in the lung, spleen, and lymph nodes. Once the host has developed circulating antibody, plasma virus is very rapidly neutralized in the circulation and transit time is reduced by several fold. Plasma viremias are usually short-lived (about a week), but there are notable exceptions.

A number of viruses replicate in cells that are found in the circulation, particularly monocytes, B or T lymphocytes, or (rarely) erythrocytes, and produce a 'cell-associated' viremia. Cell-associated viremia may be of short duration, as in the case of ectromelia and other poxviruses. However, in many instances, cell-associated virus titers are low, and viremia persists for the life of the host rather than terminating when neutralizing antibody appears.

There are several ways in which a virus might cross the vascular wall, but the precise mechanism for penetrating the blood–tissue barrier is unknown in most instances. Potential routes into tissues include passage between endothelial cells at sites where there are no tight junctions, translocation of virus-containing endosomes through endothelial cells, replication within endothelial cells, and tissue invasion of virus-infected lymphocytes or monocytes.

Some viruses can disseminate by spreading through the axons of peripheral nerves. Although less important than viremia, neural spread plays an essential role for certain viruses (such as rabies viruses and several herpesviruses) while other viruses (such as poliovirus and reovirus) can utilize both mechanisms of spread.

Localization or Tropism

One of the salient features that distinguishes viruses is their localization or tropism within the animal host. The names of individual viral diseases often reflects the organs or tissues that are involved; thus, smallpox, poliomyelitis, and hepatitis each have their characteristic features. Tropism is regulated both by viral dissemination and cellular susceptibility. Disease localization may not correspond to the distribution of infection since it reflects both the spread of the virus and the host response to infection. The localization of a virus is determined at several phases of infection, including the portal of entry, systemic spread by viremia or the neural route, and the invasion of local organs or tissues.

Most viruses are quite selective in the cell types that are infected *in vivo* and this selectivity plays a significant role in localization. One major determinant of cellular susceptibility is the presence of viral receptors, namely, molecules on the cellular surface that act as receptors for the specific virus, usually by binding a protein on the virion surface (the viral attachment protein). For instance, poliovirus can only replicate in primate tissues, because the poliovirus receptor is expressed only by primate cells. Transgenic mice expressing the the poliovirus receptor can be infected and develop typical paralytic poliomyelitis after intracerebral injection.

Cellular susceptibility also may be determined at post-entry steps in the replication cycle. An example is Newcastle disease virus, a paramyxovirus of birds. Virulent isolates of Newcastle disease virus encode a fusion protein that is readily cleaved by furin, a proteolytic enzyme present in the Golgi apparatus, so that the virion is activated during maturation prior to reaching the cell surface, and before budding of nascent virions. This makes it possible for virulent strains of the virus to infect many avian cell types, thereby increasing its tissue host range, and causing systemic infections that are often lethal. Avirulent strains of Newcastle disease virus cannot be cleaved by furin and depend upon extracellular proteases, which restricts the spread of the virus beyond the respiratory tract.

For oncogenic viruses, the tumors may represent a distant echo of virus localization. Epstein–Barr virus (EBV) infects epithelial cells and B cells. Latently infected B cells are immortalized, and, rarely, these B cells undergo further transformation into lymphomas by virtue of additional genetic events such as chromosomal transposition (t8:14).

Shedding and Transmission

Acute viral infections are characterized by brief periods (days to a few weeks) of intensive virus shedding into respiratory aerosols, feces, urine, or other bodily secretions or fluids. Persistent viruses are often shed at relatively low titers, but this may be adequate for transmission over the prolonged duration of infection (months to years). Although many viruses replicate in the skin, relatively few are spread from skin lesions. Several viruses are shed in the semen, including hepatitis B and human immunodeficiency virus. A number of viruses are excreted in colostrum and milk, including cytomegalovirus, mumps, rubella, and HIV. Blood is also an important source of transmitted virus, particularly for those viruses that produce persistent plasma or cell-associated viremias, such as

hepatitis B, C, and D viruses, HIV, HTLV-I, HTLV-II, and cytomegalovirus, and which can be transmitted by contaminated needles and transfusions. A number of viruses have been isolated from the urine but viruria is probably not important for transmission of most viruses.

Once shed, there are a several means by which a virus is transmitted from host to host in a propagated chain of infection. Probably the most important mechanism is contamination of the hands of the infected transmitter from feces, oral fluids, or respiratory secretions expelled during coughing or sneezing. The virus is then passed by hand-to-hand contact leading to oral, gastrointestinal, or respiratory infection. A second common route is inhalation of aerosolized virus. A third significant mechanism involves direct person-to-person contact (oral–oral, genital–genital, oral–genital, or skin–skin). Finally, indirect person-to-person transmission can occur via blood or contaminated needles. Common source transmissions are less frequent but can produce dramatic outbreaks, via contaminated water, food products, or biologicals such as blood products and vaccines.

Viral Virulence

Virulence refers to the ability of a virus to cause illness or death in an infected host, relative to other isolates or variants of the same agent. The study of virulence variants can provide important insights into pathogenesis, and carries the potential for development of attenuated live virus variants that can be used as vaccines. One approach to virulence is to map the genetic determinants that underlie the virulence phenotype; the other approach is a study of pathogenesis, which describes the differences in infections with viral variants of different virulence. Measures of virulence may be quantitative, or qualitative, since variants of a single virus may differ markedly in their cellular tropism, their mode of dissemination in the infected host, or the disease phenotype that they produce.

Viral Genetic Determinants of Virulence

Viral virulence is encoded in the viral genome and expressed through structural proteins, nonstructural proteins, or noncoding sequences. A large body of information about virus variants has established several principles.

1. The use of mutants has made it possible to identify the role of individual genes and proteins as determinants of the biological behavior of many viral variants.
2. There is no 'master' gene or protein that determines virulence, and attenuation may be associated with changes in any of the structural or nonstructural proteins, or in the noncoding regions of the genome.
3. The virulence phenotype can be altered by very small changes in the genome, if they occur at 'critical sites'. At such sites, a single point mutation leading to the substitution of a specific amino acid or base is often sufficient to alter virulence. For most viruses with small genomes (<20 kb), only a few discrete 'critical sites' have been discovered, usually fewer than 10 per genome.
4. It is possible to create variants with attenuating mutations at several critical sites and these may be more attenuated than single point mutants, and less prone to reversion.
5. Attenuating mutations are often host range mutations that affect replication in some cells but not in others.
6. Although many attenuating mutations have been sequenced, relatively few have been characterized at a biochemical or structural level as to their mechanism of action.

Genetic determinants of viral virulence and attenuation may be illustrated with examples from a few selected virus groups. The attenuation of the vaccine strains of poliovirus is due to critical sites, both in the 5′ nontranslated region (NTR) upstream from the long open reading frame and in selected structural and nonstructural proteins. Each of the three strains of oral polio vaccine (OPV) carry attenuating point mutations in the 5′ NTR (at positions 480, 481, or 472, in types 1, 2, and 3, respectively). Attenuating mutations at these sites are associated with reduced neurovirulence in monkeys and reduced ability to replicate in the central nervous system of transgenic mice bearing the poliovirus receptor. Each of the OPV strains carries at least one mutation that is associated with an alteration in a viral structural or nonstructural protein and confers temperature sensitivity and reduced neurovirulence, and these mutations involve different proteins for the three OPV strains. It has been suggested that mutations in the structural proteins produce attenuation via structural transitions that occur either during virion uncoating or assembly.

Bunyaviruses are negative stranded RNA viruses with a trisegmented genome. The large (L) RNA segment encodes the viral polymerase; the middle (M) RNA segment encodes two glycoproteins (G1 and G2) and a nonstructural protein, Ns_m; the small (S) segment encodes the nucleoprotein (N) and a nonstructural protein, Ns_s. Attenuation can involve either the ability of the virus to replicate in the central nervous system (neurovirulence) or its ability to cause viremia and reach the central nervous system (neuroinvasiveness). Reduced neuroinvasiveness of one bunyavirus virus strain is associated with reduced ability to replicate in striated muscle and consequent low viremogenicity. Attenuation maps to the M RNA segment encoding the viral glycoproteins suggesting that there is an alteration in the infection of myocytes (but not of neurons). Another attenuated bunyavirus showed a

striking reduction in its ability to replicate in the central nervous system of adult mice, and attenuation maps to the L RNA segment. The attenuated virus replicates poorly in C1300 NA neuroblastoma and other murine cell lines, and presumably has a mutant polymerase that restricts viral replication in neurons and certain other cell types.

Reoviruses are double-stranded 10-segmented RNA viruses. Most of the virulence determinants represent qualitative differences between type 1 Lang and type 3 Dearing in tissue and organ tropism rather than quantitative differences in disease severity

1. Reovirus type 1 Lang disseminates through the blood and causes an ependymitis in the brain while type 3 Dearing disseminates through the neural route and causes a neuronotropic encephalitis in the brain. The S1 segment encodes the σ1 protein, which is the viral attachment protein, and is the major determinant of dissemination and brain cell tropism.
2. The M1 segment encoding the μ2 protein influences replication in cardiac myocytes and myocarditis.
3. The M2 segment encoding the μ1 protein affects the protease sensitivity of the virion, and quantitative neurovirulence.
4. The L1 segment encoding λ3 protein influences replication in cardiac myocytes and myocarditis.
5. The L2 segment encoding λ2 protein influences replication levels in the intestine, titers of shed virus, and horizontal transmission between mice.

A new class of virus-encoded proteins has been recognized that contribute to the virulence of viruses by mimicking normal cellular proteins. This group of 'cell-derived' genes has been identified primarily within the genomes of large DNA viruses that have a greater capacity to maintain accessory genes than do viruses with small genomes. 'Virokines' are secreted from virus-infected cells and mimic cytokines, thereby perturbing normal host responses. 'Viroceptors' resemble cellular receptors for cytokines (including antibodies or complement components) that are thereby diverted from their normal cellular targets. Some virus-encoded proteins interfere with antigen presentation and immune induction, while others prevent apoptosis, or interrupt intracellular signaling initiated by cytokines or interferons.

Pathogenic Mechanisms of Virulence

There are many sequential steps in a viral infection and a difference in the comparative replication of two virus variants at any one of these steps can account for their relative degrees of virulence. Attenuated variants usually will replicate or spread less briskly in one or several tissues associated with the pathogenic process. A reduction in viremia can be an important mechanism for the reduction in virulence. For instance, the Mahoney strain of type 1 poliovirus causes a much higher viremia and paralytic rate than several other poliovirus strains that are less viremogenic. Different variants of a single virus can exhibit differences in their tropism for organs, tissues, and cell types, which confers a multidimensional character upon virulence. The three attenuated strains in the oral poliovirus vaccine provide an example. Both attenuated and wild-type polioviruses are able to replicate in the gastrointestinal tract to similar levels, judging from the shedding of virus in the feces, but the attenuated strains show a reduction of about 10 000-fold (relative to the wild-type strains) in their ability to replicate in the spinal cord after intraspinal injection. In this instance, virulence for the target organ (the spinal cord), rather than viremogenicity, appears to be the most important determinant of virulence.

Host Determinants of Susceptibility and Resistance

Studies with inbred animals have documented that the outcome of infections often varies in different strains of mice, and genetic analyses have been conducted to determine the form of inheritance of susceptibility, and to identify the responsible gene. Several generalizations may be made:

1. Most genetic loci control susceptibility to a specific family of viruses and not to all viruses.
2. Susceptibility can often be mapped to a single autosomal locus, but multiple loci have been identified in some instances.
3. Susceptibility may be either dominant or recessive.
4. Where loci have been mapped, they usually are distant from the major histocompatibility locus, and in most such instances, the mechanism of susceptibility is not immunological.
5. The exact mechanism of susceptibility has not been well defined in most instances, although there are some examples that map to the major histocompatibility complex (MHC), implying an immunological explanation.

It is difficult to investigate genetic determinants of host susceptibility in outbred populations of animals or humans. However, recent studies of HIV-1 have provided substantial evidence of a number of human genetic determinants of susceptibility to infection or to the rate of progression to overt AIDS. The most striking of these is a polymorphism in the gene that encodes the chemokine receptor, CCR5, which is the major co-receptor for HIV-1. Some individuals have a deletion in the gene (the Δ32 deletion) such that no CCR5 protein is expressed. Those who are homozygous for the Δ32 mutation are at very low risk of HIV infection, and those who are heterozygous for

the Δ32 deletion can be infected but have prolonged incubation periods to onset of AIDS by comparison with CCR5+ homozygous individuals.

The host response to a viral infection may also be influenced by a variety of physiological variables such as age, sex, stress, and pregnancy, all of which have been shown to influence the outcome of infection with some viruses. In general, very young animals are more susceptible than adult hosts to acute viral infections, and are more likely to undergo severe or fatal illness. The innate high susceptibility of infants born of nonimmune mothers is revealed only in those rare instances where a virus has disappeared from an isolated community so that all age groups lack immune protection. A classical example is measles, which can be a devastating disease with a mortality of up to 25% in nonimmune infants. Less commonly, advanced age can also be associated with increased susceptibility to viral infection. St. Louis encephalitis and West Nile encephalitis are examples of this phenomenon.

Viral Receptors

D J Evans, University of Warwick, Coventry, UK

Introduction

The majority of viruses have an extracellular phase in the life cycle, which is a necessary part of virus transmission and dissemination. To initiate the replication cycle for the production of progeny virions, the virus must first enter a cell. Cell entry is mediated by the specific interaction of the virus with molecules on the cell surface – the receptor – resulting in attachment, a process that leads to internalization of either part or all of the virus particle, or the genome. A cell that expresses the cognate cell-surface receptor for a virus is termed susceptible. Not all susceptible cells to which the virus binds are capable of supporting infection and replication, perhaps due to the absence of necessary intracellular components. Cells that support virus binding, entry, replication, and progeny virion release are termed permissive.

With certain notable exceptions, such as viruses of fungi that exhibit no extracellular stage in the life cycle or plant viruses introduced mechanically by insect vectors, the virus receptor therefore forms the primary determinant of virus tropism. The identification and characterization of the receptor therefore provides important insights into the early stages of the virus replication cycle, and has been a major research focus of molecular virologists worldwide.

A Definition of Virus Receptor and Co-Receptors

Our enhanced understanding of virus–receptor interactions and the early events in cell entry have demonstrated that this process is, in many cases, considerably more complicated than originally thought, involving multiple cell-surface or intracellular molecules with different roles in the entry events. A classical definition of a virus receptor would be the cell-surface molecule that mediates virus attachment and cell entry. Our current understanding of these processes demonstrates that many viruses use different molecules to mediate attachment and post-attachment entry events. For these reasons the term co-receptor is often used to indicate an accessory molecule implicated in cell entry. Both receptors and co-receptors will be considered within the scope of this article. Rather than aim to provide a complete catalog of viruses and receptors, the focus of this article is to use key examples to illustrate specific types of virus–receptor interactions and introduce the general concepts involved in receptor identification and characterization.

The Identification of Virus Receptors

Since a working definition of a receptor is a specific cell-surface molecule involved in virus attachment, the

identification of the receptor requires a means of detecting virus binding, and a requirement to demonstrate the specificity of the process.

Direct detection of a virus bound to the cell requires some form of labeling – whether metabolic labeling with a radioisotope or labeling with a conjugated fluorescent marker – and subsequent purification of the virus particle, often by density gradient centrifugation. Indirect methods of detecting virus can also be used, for example, the hemagglutination phenotype demonstrated by sialic acid binding viruses such as influenza A virus, or by detection of a bound virus with antibodies to the virus particle.

The specificity of the observed binding event typically requires the inhibition of the process using a defined block. The routine availability of monoclonal antibodies has hugely facilitated this approach to receptor identification, though alternate methods such as the use of enzymatic pretreatment of cells with heparinase or neuraminidase (NA) have also been used to demonstrate interactions with nonprotein cell-surface molecules.

Finally, in cases where the receptor is a single protein molecule, the specificity of the virus interaction can be further demonstrated by transformation of a nonsusceptible cell with DNA encoding the protein. Following expression at the cell surface, the acquisition of a virus binding phenotype is tested, perhaps combined with the demonstration of specificity by the inhibition with monoclonal antibodies. For example, the molecular cloning of the poliovirus receptor (PVR) involved expression of the protein in murine fibroblasts, which conferred susceptibility to an already permissive cell type.

Typically, a combination of the approaches outlined above is necessary to unequivocally demonstrate the identity of a virus receptor. Multiple confirmatory approaches are required as each technique has inherent uncertainties. For example, monoclonal antibodies may cross-react with closely related membrane proteins, or transformation of DNA may induce receptor expression, rather than encode the receptor *per se*. Similar techniques, and the associated caveats, are subsequently used in the initial stages of characterization of the virus–receptor interaction, for example, the receptor protein domain(s) to which the virus attaches, or the cell or tissue specificity of attachment.

Specific Examples of Virus Receptors

The examples used below illustrate a range of different types of virus–receptor interactions – those involving a single type of target molecule on the cell surface, either proteins or carbohydrate moieties, and those in which multiple receptors and co-receptors have been implicated. Due to their pivotal role in determining tissue and host tropism, and hence influence on pathogenesis, particular effort has been made in identifying receptors for important human and animal virus pathogens. However, the broad concepts illustrated below apply equally to the cell-surface proteins of bacteria used by bacteriophages – where the exquisite specificity of the interaction is used in classification and typing of *Salmonella*.

Sialic Acid

Influenza A is an enveloped virus that causes epidemic and pandemic respiratory tract infections in humans, but is naturally an enteric pathogen of aquatic birds. Both of the external virus glycoproteins are involved in interaction with the cellular receptor, sialic acid, the first identified receptor for a human virus. The trimeric hemagglutinin (HA) molecule, consisting of a stalk and globular head, carries a conserved cleft or pit at the membrane-distal end into which the sialic acid binds. Sialic acids are a family of negatively charged monosaccharides derived from neuraminic acid; those used as virus receptors are usually attached to a penultimate galactose by either an (α2,3)- or (α2,6)-linkage. The structure of an HA–sialyllactose complex has been determined at atomic resolution and provides insight into the specificity of binding, which in human strains involves (α2,6)-linked sialic acid in contrast to the binding of avian strains which exclusively interact with (α2,3)-linked sialic acid. Interaction of influenza with sialic acid is a low-affinity process, attachment being facilitated by multimeric binding to many HA molecules. The tetrameric NA virus glycoprotein has enzymatic activity that hydrolyses the glycosidic linkage of the receptor sialic acid, so enabling the release of progeny virus from the cell surface. NA-inhibitors have been developed as successful antiviral therapies.

Although influenza A is the best-characterized sialic acid-binding virus, there are many other examples, including human parainfluenza virus (hPIV) types 1–3 (and the murine hPIV analog Sendai virus), picornaviruses (rhinovirus type 67, enterovirus type 70), polyomaviruses (JC and BK virus), type 3 reoviruses, group C rotaviruses and adeno-associated virus. As with influenza A virus, predominant bias to either (α2,6)- or (α2,3)-linked sialic acid has been detected in each of these examples.

Heparan Sulfate and Other Glycosaminoglycans

Glycosaminoglycans (GAGs) (including heparan, chondroitin, and dermatan sulfate) are negatively charged sulfated sugars which are widely implicated in attachment of a range of viruses as diverse as herpes simplex virus (HSV), enteroviruses, flaviviruses, and respiratory syncytial virus. However, despite the isolation of clinical

virus isolates with GAG-binding capacity, definitive evidence that GAGs have a role in the cell infection process *in vivo* is yet to be obtained. The relevance of GAGs has been further questioned by the observation that foot and mouth disease virus (FMDV), a picornavirus that binds $\alpha_v\beta_3$ integrins *in vivo*, can readily adapt to use GAGs in cell culture – this process is discussed further below.

GAG binding is routinely demonstrated by inhibiting virus binding to the cell surface, or virus infection, with soluble analogs such as heparin sulfate, by heparinase pretreatment of cells, or by analyzing binding to cells deficient in GAG synthesis. The interaction of FMDV and heparin has also been determined crystallographically and shown to involve a region of the capsid distinct from the surface-exposed loop that binds the *in vivo* receptor, $\alpha_v\beta_3$ integrin. GAG-binding domains are usually linear or conformational regions of the virus surface that are rich in basic residues, and adaptation to GAG binding often involves the acquisition of basic (lysine or arginine) amino acid substitutions.

Most viruses shown to bind GAGs are also known to interact with at least one additional cell surface receptor. Glycoprotein C (gC) of HSV-1 and HSV-2 binds HS, and the gD interaction with certain forms of GAGs appears necessary for postbinding prefusion events in cell infection. However, gD also interacts with HVEM (herpes virus entry mediator, a member of the tumor necrosis factor receptor family) and nectins 1 and 2, suggesting that HSV may either exhibit considerable redundancy in cell-surface interactions or, interestingly, that the virus carries a number of binding activities tailored to particular cell or tissue types. Similarly, GAG-binding echoviruses appear to also require the primary receptor for entry, decay accelerating factor (DAF) (Williams and Evans, unpublished data).

The cell–receptor interactions of human immunodeficiency virus (HIV) have received particular attention. In addition to the primary receptor, CD4, and the chemokine co-receptors (see below), syndecans with GAG chains have been implicated in macrophage infection by HIV. Similarly, infection of CD4-negative microvascular endothelial cells, a probable route via which the virus gains access to the central nervous system (CNS), has been shown to be a lipid raft-independent process involving cell-surface proteoglycans. Again, as with HSV, the complexity of interaction with multiple cell receptors, and the *in vivo* function, is yet to be satisfactorily dissected.

Histo-Group Antigens as Receptors

The wide range of nonprotein molecules used for attachment by viruses also includes the histo-blood group antigens (HBGAs), which serve as receptors for the noroviruses, positive-strand RNA viruses that cause acute gastroenteritis. HBGAs are complex carbohydrates present both as free oligosaccharides and attached to the surface of mucosal epithelia. The HBGA phenotypes of humans are polymorphic and complex, and are associated with multiple gene families. This was consistent with the demonstration that norovirus infection was influenced by both prior acquired immunity and the genetic background – patients with blood group O were significantly more susceptible to infection than those with blood group B. Subsequent binding studies with norovirus virus-like particles (VLPs) – which retain the receptor-binding capacity of the virus which cannot be cultured *in vitro* – and specific antibodies to blood-group antigens, soluble blood-group antigens or glycosidases, have confirmed a role for these molecules in virus attachment.

Immunoglobulin Superfamily Proteins

Our understanding of the range of cell-surface proteins that function as virus receptors is influenced by the methods utilized to identify the protein. Since these methods are predominantly geared to isolating single-gene traits, for example, cDNA library screening, it is unsurprising that the majority of proteins definitively identified as receptors are single proteins, rather than one component of a multiprotein complex. Perhaps reflecting their relative abundance at the cell surface, proteins belonging to the immunoglobulin superfamily are implicated in the attachment of many viruses.

Poliovirus, the causative agent of paralytic poliomyelitis, binds the membrane-distal Ig-like domain of CD155, the PVR. Receptor binding initiates a series of irreversible conformational changes in the virus particle, which results in the externalization of capsid proteins usually hidden in the mature infectious particle, and the delivery of the virus genome to the cell cytoplasm. Data are accumulating to suggest that this process involves formation of a pore traversed by the genome, though other models exist. That PVR is sufficient to mediate these processes has been elegantly demonstrated by several methods; PVR expression in murine cells renders them fully permissive for poliovirus infection, and is the basis for the generation of PVR-transgenic mouse lines for neurovirulence studies, the conformational changes observed at the cell surface can be recapitulated using poliovirus and soluble PVR (sPVR) *in vitro*, and – most recently – the bound virus–receptor complex has been visualized by crystallography and, using cryo-EM, studied at the surface of PVR-loaded membrane vesicles.

Human rhinoviruses are very closely related to members of the enterovirus genus to which poliovirus belongs. The rhinoviruses can be divided into two predominant groups based upon their receptor usage; of these, the major receptor group bind to the membrane-distal Ig-like domain of intracellular adhesion molecule type 1 (ICAM-1). Like poliovirus, receptor binding initiates

conformational changes in the rhinovirus particle that are considered essential for infection. A further similarity is the region of the capsid involved in the receptor interaction. In both poliovirus and the major group rhinoviruses, the receptor binds to a canyon or cleft surrounding the fivefold axis of icosahedral particle symmetry. Two decades ago, Rossmann proposed that this canyon is too narrow to allow the binding of virus neutralizing antibodies, thereby allowing the virus to retain a relatively invariant receptor-binding domain in the presence of immunoselection. More recent crystallographic studies have demonstrated that some neutralizing antibodies penetrate deep into the rhinovirus canyon. This suggests that the canyon has less to do with evasion of immune surveillance, but has instead evolved in response to receptor binding requirements and to accommodate the structural changes that occur post-binding.

The Ig-like protein that has received some of the most intense scrutiny is CD4, the primary receptor for HIV. The identification of CD4 as a receptor for HIV went some way to explain the tropism and pathogenesis of the virus; CD4+ T cells were often depleted in HIV-infected individuals. Antibodies to CD4 blocked virus attachment, fusion and infection, and expression of CD4 in murine cells permitted virus binding. Detailed analysis using monoclonal antibodies specific for each Ig-like domain of CD4, and subsequent site-directed mutagenesis of the receptor, demonstrated that the attachment protein of HIV (the virus surface glycoprotein gp120) binds to a surface-exposed loop of the most membrane-distal of the four Ig-like domains of CD4. Gp120 carries the conserved CD4 attachment site which is protected, though not completely hidden, from interaction with neutralizing antibodies by the diversity, conformational flexibility, and heterogeneous glycosylation of the surrounding protein. One characteristic exhibited by HIV-infected long-term nonprogressors is the presence of a potent neutralizing antibody response to the CD4 binding site – because the virus must retain a largely invariant receptor-binding domain, these antibodies are active against divergent virus isolates, and significant effort has been expended in generating vaccine candidates capable of inducing a similar immune response. Other therapeutic approaches based upon the conserved interaction of gp120 and CD4 have been investigated. Although soluble CD4 receptors, lacking the transmembrane domains, block HIV infection *in vitro*, they have been largely ineffective in clinical trials. These disappointing results have been attributed to the need to maintain high serum concentrations of a protein with a short half-life, and the ability of the virus to spread directly from cell to cell by fusion, rather than by extracellular virus. Similarly, approaches involving toxins fused to soluble CD4 that are used to target gp120 expressed at the surface of infected cells have only been promising in *in vitro* assays.

Complement Control Proteins as Virus Receptors

A number of viruses have been shown to bind to complement control proteins, also termed the regulators of complement activity (RCA) family proteins. These proteins, characterized by a two-disulfide protein fold termed a short consensus repeat (SCR), are involved in protecting autologous cells from complement-mediated lysis.

Epstein–Barr virus (EBV) attachment to B lymphocytes occurs by the interaction of the virus gp350/220 envelope glycoprotein with the cell-surface C3dg receptor designated CR2 (CD21). CR2 was identified as the receptor following the observed similarity between gp350/220 sequences and C3dg, the complement protein target for CR2 activity. Further supporting evidence included the demonstration that multimerized peptides of the proposed gp350/220 or C3dg binding domains inhibited attachment, and the receptor identity was confirmed by expression studies in CR2-deficient target cells. CR2 possesses 16 extracellular SCR domains, the two most membrane-distal being the site of gp350/220 binding, as demonstrated by the construction of murine-human CR2 chimeric receptors, and using SCR-specific monoclonal antibodies in blocking studies.

Laboratory-adapted measles virus binds another RCA family protein member, CD46, a four-SCR domain protein that acts as a cofactor in the proteolytic inactivation (and hence cell protection) of C3b/C4b. Antisera to CD46 blocks virus binding and infection, and transfection of rodent cells with CD46 renders them susceptible to infection by the Edmonston and Hallé strains of measles virus. Further studies demonstrated that clinical isolates of measles cultured in human B-cell lines exhibited a cell tropism inconsistent with the use of CD46 as the receptor – further details are provided in the section on laboratory adaptation.

DAF, a 55 kDa RCA-family protein, is the receptor for a significant number of human enteroviruses, including the coxsackie B viruses and many echoviruses. In contrast to many of the other examples presented here, where binding is to the membrane-distal domain of the receptor, the majority of the known DAF-binding enteroviruses interacts with the third SCR, together with the second and/or fourth SCR domains. Recent completion of the atomic structure of DAF shows it to be a rod-shaped protein, with the four SCR domains projecting in a broadly linear fashion from the top of a heavily glycosylated Ser/Thr-rich stalk, which distances the complement-control functions from the cell membrane. Unsurprisingly, considering the receptor structure, interaction of DAF with echoviruses does not involve the canyon on the virus surface, but instead occurs across the twofold axis of symmetry, with the receptor interface occupying a surface-exposed region of the capsid. In the case of the coxsackieviruses, DAF binding serves both to

attach the virus to the cell surface and initiate a cascade of signaling events which results in the transport of the virus to the co-receptor for infection – CAR, the coxsackie and adenovirus receptor, which is located at tight junctions and not normally accessible to the virus.

Co-Receptors for Infection

The distinction between a receptor and a co-receptor for infection is largely semantic. As our understanding of virus binding and entry improves, it is clear that this is often a multistage process involving a cascade of interactions between the virus and cell-surface proteins. The initial interaction is usually defined as being to the receptor, with subsequent interactions being mediated by co-receptors. This order can be reversed if the first interaction is a relatively nonspecific event – for example, the binding of HSV to HS – in which case co-receptor binding may be considered to temporally precede interaction with a more specific molecule that perhaps defines the cell or tissue tropism of the virus. Therefore, the discrimination between nonspecific attachment molecules, receptors, and co-receptors – in which all are sometimes required for infection – is open to interpretation. What is clearly important for many viruses is the requirement for a range of interactions between the virus and the cell surface. Indeed, as our understanding of virus infection improves, the number of examples in which a single receptor is implicated – such as poliovirus – is dwindling, and may represent the exception, rather than the rule.

Although the coxsackie B viruses bind DAF at the cell surface, infection also requires CAR, an Ig-superfamily protein with two extracellular domains, which interacts with the canyon of coxsackie B viruses or the fiber of adenovirus types 2 and 5. Like the poliovirus–PVR interaction, binding of coxsackie B viruses to CAR – at the cell surface or in solution – triggers the irreversible conformational changes associated with particle uncoating. However, CAR is naturally located in tight junctions where it mediates homotypic cell adhesion, and is therefore not immediately accessible for virus attachment at the apical cell surface. Recent elegant studies have demonstrated that virus binding to DAF at the latter site results in Abl-kinase mediated signaling events which cause actin rearrangements that allow virus movement to the tight junctions where uncoating occurs. DAF binding also activates Fyn-kinase, which results in the phosphorylation of caveolin and subsequent virus entry in caveolin vesicles. The coxsackie B viruses therefore exploit the signaling capacity of their low-affinity receptor (DAF) to traffic to the high-affinity, uncoating receptor (CAR) and thereby cross the epithelial barrier.

Like poliovirus and rhinovirus, binding of HIV to CD4 initiates conformational changes in the trimeric gp120 that are a prerequisite for the subsequent fusion events. However, unlike the two picornavirus examples, HIV must also interact with a co-receptor as a necessary precursor to the fusion of viral and cellular membranes. This requirement for a co-receptor explains why HIV can bind to human CD4 expressed on murine cells – which lack the co-receptor – without undergoing membrane fusion. A mouse-CD4 cell line was transformed with a human cDNA library and used to functionally screen for additional proteins which would enable gp120-mediated membrane fusion. This, or analogous, screens were used to define the co-receptor for HIV as one of a related series of receptors for chemotactic cytokines such as RANTES, MIP-1α and MIP-1β. The chemokine receptors identified, CXCR4 or CCR5, belong to the seven-transmembrane-domain G-protein-coupled receptor superfamily. Co-receptor specificity appears to be determined by the third hypervariable domain (V3) of gp120 – a target for potently neutralizing antibodies *in vitro* – with an additional conserved domain of gp120 contributing to generic features of the chemokine receptor attachment. The critical conserved residues of the latter domain remain hidden from immune surveillance until exposed by the structural changes in gp120 that occur as a consequence of CD4 binding. The importance of the chemokine co-receptor in HIV infection is supported by the observed genetic resistance to HIV of individuals with a deletion and frameshift within CCR5. Similarly, co-receptor identification provided an explanation for the observed suppression of HIV infection by the chemotactic cytokines released by CD8+ T cells. Finally, the identification of chemokine receptors as critical co-receptors of HIV infection has also contributed to our understanding of virus tropism and evolution *in vivo*. CCR5-tropic strains of HIV are predominant for transmission and during the asymptomatic phase of virus infection. CCR5 is expressed at high levels in activated/memory cells and in gut-associated lymphoid tissue, the primary site of HIV replication. As infection progresses, CXCR4-tropic viruses evolve, able to exploit the wider tissue expression of the CXCR4 receptor. The, perhaps logical, assumption that this broadening of cell and tissue tropism is the cause of disease progression is contradicted by the failure to observe a switch to CXCR4-tropic viruses in a significant proportion of patients with acquired immune deficiency syndrome (AIDS).

Laboratory Adaptation and Receptor Usage by Clinical Virus Isolates

Due to the possession of error-prone replication strategies, many viruses exhibit an exquisite ability to adapt to the environment in which they are grown – for example, by the generation of mutations that confer resistance to

neutralizing antibodies. The same variation can confound the correct identification of virus receptors in laboratory studies, due to the adaptation to alternate receptors for cell attachment and entry.

The example of heparan sulfate binding by FMDV has already been used to illustrate this process. HS-adapted FMDV isolates are apathogenic in animals, presumably reflecting the evolutionary adaptability of the virus to an environment in which receptor usage is not a rate-limiting process in infection, transmission, or dissemination. The virus interacts with the *in vivo* receptor ($\alpha_v\beta_3$ integrin) using a conserved Arg-Gly-Asp amino acid triplet (RGD motif) on a surface-exposed loop of the VP1 capsid protein. Laboratory-adapted HS-binding FMDV strains can dispense with $\alpha_v\beta_3$ integrin binding altogether, as demonstrated by the use of reverse genetics to mutate the RGD motif to another sequence. Being acid-labile, it is likely that uncoating of FMDV is mediated by entry of the virus–receptor complex into an endosome. This is supported by the further demonstration that it is possible to engineer anti-FMDV antibodies onto the cell surface to which the virus is bound, and via which infection can occur in the absence of either HS or integrin binding.

CD46, like most other complement-control proteins, is expressed ubiquitously on serum-exposed cells. Clinical isolates of measles virus, isolated in either B95a cells or human B-cell lines, do not infect all CD46-expressing cell lines, suggesting that they may use an alternate receptor. Subsequent functional expression cloning studies resulted in the isolation of a cDNA encoding human SLAM (signaling lymphocyte-activation molecule; also known as CDW150) that conferred susceptibility to B95a-cell cultured measles virus. SLAM is an Ig-superfamily protein expressed on a range of immune system cells (macrophages, dendritic cells, some B and T cells) that, when liganded to SLAM on an adjacent cell, transduces a signal resulting in T_H2 cytokine (IL13 and 4) production. All measles virus isolates tested can infect cells via SLAM, though some – including the lab-adapted Edmonston strain – can also use CD46. However, studies suggest that CD46 binding is irrelevant *in vivo* and arises upon culture by the substitution of as few as a single amino acid in the HA protein of the virus.

Summary

Virus receptors are key components of the early events involved in cell infection. The examples outlined above should illustrate that the definition of receptors acting solely as attachment molecules is overly simplistic. In addition to attachment, receptors also actively contribute to entry by initiating conformational changes in the virus that lead to uncoating. In addition, they provide mechanisms for internalization – which increasingly appear to involve signaling events that occur upon receptor binding – in which the virus may subvert a natural receptor cycling process. Furthermore, the identification of virus receptors contributes significantly to our understanding of host, tissue, and cell tropism, and helps explain aspects of virus pathogenesis. The selected bibliography provides further examples illustrating aspects of virus receptor identification and function.

Glossary

Dicer, or Dicer-like (DCL) enzymes RNAse III or RNAse-III-like enzymes responsible for digesting the noncoding regions of mRNAs to produce 21–24 nt single-strand RNAs known as miRNAs and siRNAs.
Green fluorescent protein (GFP) This is derived from jellyfish and fluorescence green. Excitation wavelength is 488 nm and emission is above 520 nm. Fusions involving GFP are often used to study protein subcellular targeting or distribution in tissues.
MicroRNAs (miRNAs) Single-strand RNAs that are 21–24 nt in length are found in eukaryotes and arise from noncoding regions of transcripts. These are produced by nucleolytic processing by DICER, and RNAse-III-like enzyme. These are crucial components of the RNAi pathway.
RNA interference (RNAi) Similar to post-transcriptional gene silencing. More specifically, cellular or synthetic small RNA molecules can target homologous mRNA for degradation thereby preventing gene expression.
RNA silencing or post-transcriptional gene silencing (PTGS) Mechanism regulating gene expression by regulating RNA accumulation after transcription. Mechanism involves RNA degradation machinery to shut off gene expression.
Short interfering RNAs (siRNAs) Double-strand RNAs that are 21–24 nt in length which are generated by DICER or Dicer-like enzymes. SiRNAs can spread systemically in *C. elegans* and may cause silencing in distal organs. Some single-strand RNAs are made double-strand by RNA-dependent RNA polymerases. These double-stranded products are then cleaved by DICER.
Transcriptional gene silencing (TGS) Silencing of genes in the nucleus. A small RNA molecule triggers *de novo* DNA methylation thereby blocking transcription. Small RNA typically is homologous to the target gene.
Virus-induced gene silencing (VIGS) Viral RNAs can trigger for PTGS similar to small RNAs. Several plant viruses have been engineered as vectors for use in experiments shutting off gene expression by PTGS. Fragments of genes, antisense RNAs, small RNAs can be introduced into the viral vector and silencing is induced upon inoculation with the recombinant virus.

Introduction

RNA silencing, also known as post-transcriptional gene silencing (PTGS) or RNA interference (RNAi) is a mechanism regulating gene expression in a wide range of eukaryotes. RNA silencing is a mechanism in which small RNAs block gene expression by targeting homologous mRNAs without impacting nuclear DNA. Andrew Hamilton and David Baulcombe first showed that short antisense RNAs of 20–25 nt which share homology with target mRNAs are produced in silenced tissues. Since 1999 additional short RNAs have been identified, including microRNAs and siRNAs, which target homologous RNA sequences either for sequence specific degradation or, in some instances, function to repress mRNA translation.

PTGS is induced by double-stranded RNAs in most eukaryotic systems. Since most RNA viruses form double-stranded RNA replication intermediates, replicating viruses often trigger PTGS, which subsequently degrades all homologous RNAs within the cell. This has led researchers to suggest that PTGS may have originally evolved as an antiviral defense mechanism. The ability of PTGS to target viral RNAs for degradation was demonstrated in the early 1990s when transgenic plants expressing untranslatable transcripts of the viral coat protein or replicase gene were found to be resistant to infection by the homologous virus while remaining susceptible to unrelated viruses. Virus resistance was also reported in experiments using transgenic plants which failed to accumulate detectable levels of the transgenically expressed coat protein RNA.

The laboratory of William Dougherty provided the first reports of transgenic plants recovering from virus infection. A set of transgenic tobacco plants expressing a nontranslatable tobacco etch virus (TEV) coat protein RNA were initially susceptible to virus infection but then recovered and became highly resistant to secondary inoculation. Viral RNA was undetectable and transgene RNAs showed lower steady-state level accumulation in recovered leaves indicating that an RNA degradation mechanism was triggered. Contemporary studies by Rob Goldbach's laboratory showed that nontranslatable transcripts for the tomato spotted wilt virus N protein-protected transgenic plants from infection by the virus. The idea that viruses trigger a cellular antiviral defense pathway which degrades homologous RNAs was further supported by experiments in the laboratory of

David Baulcombe showing that recovery can occur during infection of nontransgenic tobacco plants. *Nicotiana clevelandii* inoculated with the nepovirus tomato black ring virus (TBRV) strain W22 initially showed clear virus symptoms but later recovered. Plants were resistant to secondary inoculation with the same W22 strain but were susceptible to inoculation with the heterologous nepovirus, tobacco ringspot virus (TRSV), and showed partial protection to secondary infection with the TBRV strain BUK. Insertion of a fragment of the TBRV genome into the potato virus X (PVX) genome was sufficient to block infection of PVX in recovered plants indicating that plants contain an inducible sequence-specific degradation mechanism that may be a component of the plant immune response to RNA virus infection.

This same PTGS mechanism also provides cross-protection against secondary virus infection seen in the TBRV and PVX experiments described above and in experiments showing that plants recovered from infection with tobacco rattle virus containing GFP (TRV-GFP) were resistant to secondary infection with PVX-GFP. Technology based on PTGS has been developed to engineer virus resistance in transgenic plants.

Viral-induced gene silencing (VIGS) in transgenic plants can result in methylation of the cognate transgene or nuclear gene. It has been suggested that *de novo* DNA methylation triggered by transcriptional gene silencing (TGS) or PTGS is driven by siRNAs imported into the nucleus, which recruit DNA methyltransferases to similar target sequences. Thus, RNA viruses, such as PVX or tobacco rattle virus (TRV), have been engineered as vectors used for knocking out host gene expression. These are termed VIGS vectors. Entire genes or fragments of genes can be inserted into the viral vector and following inoculation, induce silencing of the cognate endogenous gene. One of the earliest examples of VIGS targeting an endogenous gene was insertion of the phytoene desaturase gene (PDS) into PVX. PDS is involved in carotenoid biosynthesis and affects plants' susceptibility to photobleaching. Virus-induced PDS silencing causes leaves to lose all green color and bleach white under normal lighting conditions. The most popular research tools to study TGS and PTGS are transgenic plants expressing the green fluorescent protein (GFP) and PVX or TRV vectors containing fragments of the GFP coding sequence. GFP expression can be monitored using a UV lamp and over time GFP expression disappears throughout the entire plant. In 1997, Olivier Voinnet and David Baulcombe first reported GFP-transgene silencing by an RNA virus and also demonstrated the silencing signal can spread systemically to suppress gene expression in distal regions. Thus, the use of VIGS to suppress expression of endogenous genes has become an important tool for analysis of gene function.

DNA viruses can also be used as gene silencing vector. The chalcone synthase gene, which is involved in flower pigmentation in *Petunia hybrida* flowers, was inserted into tobacco yellow dwarf virus genome and flower pigmentation was completely altered in virus infected petunia. Cabbage leaf curl virus (CabLCV), a member of the genus *Begomovorus* of the family *Geminiviridae*, has been engineered to express any endogenous targeted gene of *Arabidopsis* and proved to be an efficient tool for scientists studying gene expression in this model plant. Similarly, the African cassava mosaic virus (ACMV), another begomovirus, modified to be a silencing vector, was demonstrated to be able to silence a variety of endogenous genes in cassava, thereby providing a useful tool to breeders for that crop.

Viral-Derived Short Interfering RNAs

Small RNAs of approximately 21–24 nt are found in all eukaryotes and belong to two general classes: microRNAs (miRNAs) and short interfering RNAs (siRNAs). miRNAs are 21–24 nt ssRNAs and arise from nonprotein coding regions of transcripts which are nucleolytically processed by an RNAse-III-like enzyme called DICER in animals and *Caenorhabditis elegans*, or DICER-like (DCL) in *Arabidopsis*. siRNAs similar to miRNAs range in size from 21 to 24 nt, but are dsRNAs derived from longer double-stranded RNA (dsRNA), including RNAs containing inverted repeats or replicative forms of RNA viruses.

Animals and *C. elegans* encode only a single DICER while *Arabidopsis* encodes four DCL proteins. While studies in *Drosophila* and plants show that DICER plays a role in antiviral defense, currently there is no direct evidence that RNA silencing acts as a natural antiviral defense mechanism in vertebrates. Dicer 2 mutants in *Drosophila* are hypersusceptible to virus infection. All four DCL proteins in *Arabidopsis* are involved in generating siRNAs from DNA and RNA viruses. DCL1 and DCL4 proteins produce 21 nt siRNAs, DCL2 produces 22 nt siRNAs, and DCL3 produces 24 nt siRNAs. While reports show all four DCL proteins contribute to the production of siRNAs from geminiviruses (CaLCuV) and pararetroviruses (cauliflower mosaic virus; CaMV) in plants, DCL2 and DCL4 generate siRNAs for defense against RNA viruses.

Cellular RNA-dependent RNA polymerases (RDR) also contribute to the formation of siRNAs. Single-stranded RNAs are made double stranded by cellular RDRs and then are cleaved by DICER to produce siRNAs. *HEN1* encodes a methyltransferase which acts alongside the DCL proteins to methylate the 3′-terminal nt protecting siRNAs from degradation. siRNAs then guide sequence-specific RNA-induced silencing complexes (RISCs) to target sequences for degradation. The RISC is comprised of several proteins including *ARGONAUTE* (*AGO*), which bind siRNAs or target sequences. RDR proteins use the siRNAs as primers for

synthesis of dsRNAs from target viral RNAs. *Arabidopsis* encodes three *RDR* genes named *RDR1*, *RDR2*, and *RDR6*. *RDR1* is salicylic acid inducible. *Arabidopsis* plants showing defects in RDR1 show increase susceptibility to TMV and TRV. *RDR6* is also known as *SDE1* or *SGS2* and is required for transgene-generated short RNAs. *SDE5* is a factor recently identified which acts with *RDR6* to generate dsRNAs. *SDE5* may function in the nuclear transport of dsRNAs produced by *RDR6*. Mutant plants deficient in *RDR6* show increased susceptibility to cucumber mosaic virus (CMV) but not to other viruses.

Research in plants and in *C. elegans* first showed that a systemic silencing signal which spreads to distal organs is likely to be an siRNA or dsRNA. Research has shown that 21 nt siRNAs can spread 10–15 cells in tobacco and *Arabidopsis* plants. For more extensive movement, additional rounds of signal amplification are needed to produce a second generation of siRNAs. A model of transitive RNA silencing was proposed by Voinnet and colleagues in 2003 in which dsRNAs are synthesized *de novo* by RDR6, which are then cleaved by DICER to generate the second generation of 21 nt siRNAs. Cycles of siRNA propagation and movement into neighboring tissues lead to general silencing throughout surrounding tissues. Systemic silencing spread was proposed to rely on vascular transport of longer 25 nt siRNAs.

RNAi-Based Antiviral Therapies

Viral siRNAs accumulate to significant levels in plants and insects but have not been characterized in human cells infected with any RNA viruses. However, synthesized siRNAs have been shown to block replication and accumulation of a wide range of animal RNA and DNA viruses in cell cultures and vertebrate systems. There are examples of siRNAs targeted to specific sequences in the genomes of viruses including poliovirus (PV), foot and mouth disease virus (FMDV), hepatitis virus A (HVA), influenza virus, SARS-COV, HIV, and hepatitis virus B (HVB) which reduce virus titer and inhibit replication in cell cultures and in mice. Researchers using synthesized RNAs targeting different viral RNA sequences reported this strategy to be a successful form of antiviral therapy. For monopartite RNA viruses such as PV, FMDV, HVA, short RNAs targeting conserved sequences corresponding to genes encoding structural proteins or the viral replicase have been successful.

One of the important issues in developing RNAi therapeutics has been the pressure on target sequences to mutate which causes the virus to escape the suppressive activity of the siRNA molecule. To address this concern researchers have relied on bioinformatics tools and GenBank database to search entries of virus sequences to identify highly conserved nucleic acid elements ranging from 21 to 25 nt in length. Comparisons among virus isolates have been crucial for determining the most conserved regions. Among viruses, which have high mutation rates, therapies combining synthesized short RNA molecules targeting several conserved sequences have been most effective at reducing the occurrence of escape viruses.

The polyomavirus Simian virus 40 (SV40) as well as members of the family *Herpesviridae* including Epstein–Barr virus (EBV), herpes simplex virus 1 (HSV-1), Kaposi's sarcoma-associated virus (KSHV), and were found to encode miRNAs. At least 23 miRNAs have been identified in EBV-infected lymphocytes, many of which map to the BART gene. All BART gene miRNAs accumulate mainly during latency suggesting that they likely play a role in this stage of infection. KSHV is also associated with lymphomas and 12 miRNAs have been identified in latent infected cells. For KSHV a different set of miRNAs are seen during lytic infection suggesting that specific miRNAs are expressed during different stages of the viral life cycle. Viral-encoded miRNAs function to regulate viral gene expression and to downregulate host transcription. Since many of the herpesviral miRNAs associate with latency, they likely play a role in enabling the virus to evade the host immune system for many years. Further research is needed to find out if viral miRNAs affect tumorogenesis and if RNAi technology can be used to alter the onset of cancer.

Viral Suppressors of RNA Silencing Counter Cellular Defenses to Promote Infection

Plant and insect viruses encode silencing suppressor proteins which inhibit one or more steps in the miRNA or siRNA degradation pathway, thus countering the antiviral defense machinery. Many silencing suppressors bind dsRNA, siRNAs, and miRNAs. The potyvirus HC-Pro blocks the RISC from acting on target RNAs (**Figure 1**). HC-Pro was the first identified suppressor of RNA silencing in plants and was discovered by researchers studying viral synergistic diseases. Synergism is a phenomenon in which one virus shows increased titer and symptom induction due to the presence of a second but unrelated virus. Many, but not all, examples of synergy involve co-infection in which one of the viral partners is a potyvirus. Building on the early studies of PVX/PVY synergy, Vicki Vance, James Carrington, and their colleagues carried out further investigations of PVX/PVY synergy at the molecular level. They examined virus-specific RNA production in doubly infected plants and used PVX-derived vectors and transgenic plants to express segments of PVY and other potyviral genomes. Transgenic plants expressing the potyviral P1/HC-Pro sequence developed the same synergistic response when inoculated with unrelated

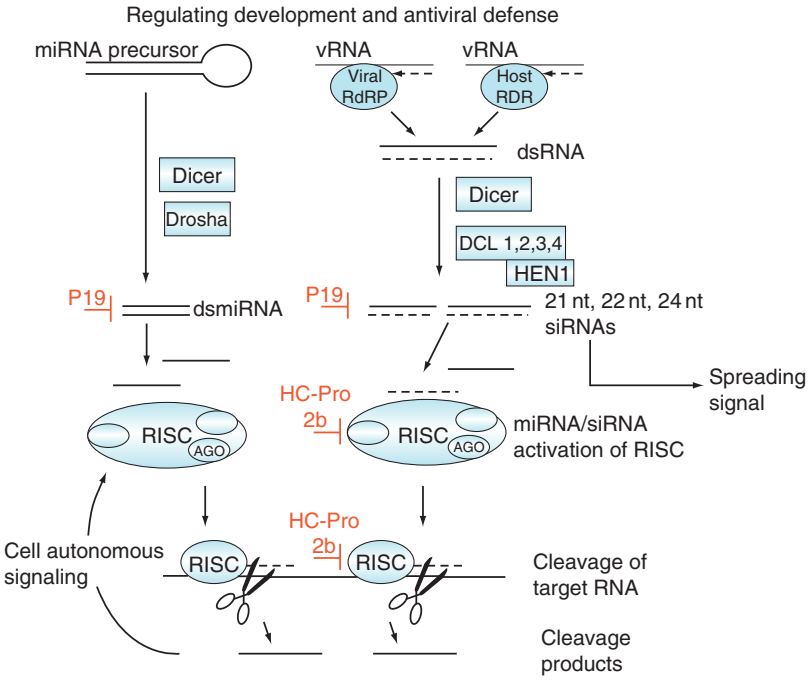

Figure 1 Model for RNA silencing updated from Himber C, Dunoyer P, Moissiard G, Ritzenthaler C, and Voinnet O (2003) Transitivity-dependent and -independent cell-to-cell movement of RNA silencing. *EMBO Journal* 22(17): 4523–4533; Matzke MA and Matzke AJ (2004) Planting the seeds of a new paradigm. *PLoS Biology* 2: E133; Blevins T, Rajeswaran R, Shivaprasad PV, *et al.* (2006) Four plant Dicers mediate viral small RNA biogenesis and DNA virus induced silencing. *Nucleic Acids Research* 34(21): 6233–6246. Double-stranded RNAs (dsRNAs) are produced either by hairpin interactions or by viral and host RNA-dependent RNA polymerases which synthesize complementary RNAs using viral RNA (vRNA) or mRNA templates. Dicer or Dicer-like proteins cleave the dsRNAs to smaller miRNAs or siRNAs which then guide the RISC complex to the target RNAs. Target RNAs are cleaved into short RNAs which can interact with the RISC complex to continue the cycle of cell autonomous RNA degradation. Some siRNAs are diverted prior to the RISC complex and move cell-to-cell and long distance to perpetuate silencing in surrounding and distal tissues. Examples of viral silencing suppressors are identified in red which block silencing by acting on the siRNAs or RISC complex.

viruses such as PVX, TMV, and CMV. P1/HC-Pro silencing suppression was demonstrated by crossing the transgenic plants with transgenic plants that were silencing for the GUS gene. The progeny lines showed restored GUS expression indicating that P1/HC-Pro suppressed transgene silencing. In a second set of experiments the GFP transgene was silencing by PVX vector containing GFP. When P1/HC-Pro was added, GFP expression was restored. Contemporaneously with this work, it was shown that CMV is also able to counteract RNA silencing and that this is mediated by the CMV 2b protein.

A reversal of silencing assay was developed for identification of viral silencing suppressor proteins. This assay uses the GFP expressing *Nicotiana benthamiana* line 16c which is susceptible to GFP silencing by infiltrating leaves with a suspension of *Agrobacterium* carrying the GFP gene. This induces silencing of GFP throughout the entire plant. GFP expression is restored to silenced plants following infection with PVX containing a gene for a silencing suppressor. Variations on this approach include grafting of transgenic plants that are silenced for reporter gene expression to scions that are transgenic for the same reporter gene and for the candidate silencing suppressor protein. This approach was used to demonstrate that the CMV 2b protein inhibits systemic silencing in plants. Using this approach a wide number of viral silencing suppressor proteins have been identified (**Table 1**). Remarkably, some viruses encode more than one silencing suppressor. For example, citrus tristeza virus encodes at least three proteins with silencing suppressor activity, which can confound attempts by the host at generating resistance to the virus.

In general, silencing suppressor proteins inhibit production of siRNAs. Many silencing suppressor proteins bind siRNAs preventing their incorporation into the RISC. The tombusvirus p19 is one example whose crystal structure was recently described. *In vitro* assays show that p19 binds 21 nt siRNAs. The potyvirus P1/HC-Pro acts to block the RISC reducing siRNA accumulation while enhancing miRNA accumulation. The cucumovirus 2b inhibits the spread of the silencing signal but also accumulates in the nucleus where it interferes with silencing-induced DNA methylation.

Several viral silencing suppressor proteins have cross-kingdom activity, that is, they are able to suppress RNA silencing in both insect and plant cells. In a seminal

Table 1 Viral silencing suppressors (April 2007)

Host	*Genome*	*Virus genus*	*Virus name(s)*	*Suppressor(s)*	*Other name/function(s)*
Plant	DNA	*Begomovirus*	Tomato leaf curl virus	C2	Transcriptional activator
			Tomato yellow leaf curl virus	C2	Adenosine kinase inhibitor
			African cassava mosaic virus	AC2, AC4	
			Mungbean yellow mosaic virus	AC2	
			Tomato golden mosaic virus	AL2	
		Curtovirus	Beet curly top virus	L2	
	(+) ssRNA	*Aureusvirus*	Pothos latent virus	P14	
		Benyvirus	Beet necrotic yellow vein virus	P14	Regulate RNA2, CP accumulation
				P31	Enhance P14 activity in roots

Updated from tables collated by Bucher E, Lohuis D, van Poppel PM, Geerts-Dimitriadou C, Goldbach R, and Prins M (2006) Multiple virus resistance at a high frequency using a single transgene construct. *Journal of General Virology* 87: 3697–3701; Li F and Ding SW (2006) Virus counterdefense: Diverse strategies for evading the RNA-silencing immunity. *Annual Review of Microbiology* 60: 503–531; Palukaitis and MacFarlane (2006); and Silhavy D and Burgyan J (2004) Effects and side-effects of viral RNA silencing suppressors on short RNAs. *Trends in Plant Science* 9: 76–83.

study, the group of S.W. Ding used both transgenic plants harboring silenced reporter genes and cultured insect cells to demonstrate that the B2 protein of flock house virus (FHV), an insect-infecting virus, was a silencing suppressor. Since then, a variety of insect and vertebrate-infecting, as well as fungus-infecting, viruses have been shown to encode proteins with RNA silencing activity under various assay conditions (**Table 1**). However, the results obtained by assaying viral proteins for silencing suppression in nonhost systems need to be interpreted with caution. For example, the influenza virus NS1 protein, which inhibits the interferon system in human cells, also inhibits RNA silencing in plants and in drosophila cells but not in HeLa cell cultures.

Recently, Deleris and colleagues created lines of *Arabidopsis thaliana* plants carrying single or multiple mutant alleles of the *DCL* genes. These plants offer an additional and less ambiguous method for identifying silencing suppressors, at least for plant viruses. This is illustrated by experiments using a turnip crinkle virus (TCV) derivative in which the coat protein gene, which also functions as a silencing suppressor, was replaced by a *GFP* gene. Compared to wild-type TCV, this modified virus is compromised in movement and symptom induction. However, symptom induction and systemic movement were restored in double *dcl2–dcl4* mutant plants; to the same extent seen in plants constitutively expressing a transgene encoding TCV coat protein.

Viroids are infectious small circular RNAs which do not encode a protein and rely on host DNA-dependent RNA polymerases for replication. Biao Ding's laboratory detected small 21 nt RNAs that are seen in PSTVd-infected plants and are active in RISC-mediated cleavage of target RNAs containing the GFP coding sequence fused to a homologous RNA segment, but the small RNAs do not impact PSTVd accumulation. While further experiments found no indication that PSTVd RNA suppresses silencing, experiments showed that PSTVd secondary structure blocks RISC-mediated cleavage. Thus, instead of suppressing RNA silencing, secondary structure of the PSTVd genome provides protection against degradation by the silencing machinery.

Silencing Suppressors Affect Plant Development

Many plant viral suppressors of RNA silencing have the ability to cause disease by altering the normal course of plant development. This was revealed by analysis of mutant viruses. For example, naturally occurring mutations in the gene for the TMV 126 kDa replicase protein result in a masked (symptomless) phenotype which relates to decreased viral silencing suppression activity and rate of systemic movement. Site-specific mutations introduced into the tobacco vein mottling virus (a potyvirus) HC-Pro gene also altered symptom expression. More drastic forms of mutagenesis, such as complete deletion of the 2b protein gene, created CMV strains that did not induce symptoms.

Transgenic plants expressing known or candidate viral silencing suppressor genes have been used to characterize the effects of the protein on plant gene expression, metabolism, and development, in the absence of virus infection. In most cases, stable expression of RNA silencing suppressors such as potyviral P1/HC-Pro proteins, tombusviral P19 proteins, beet yellows virus P21 protein, TCV CP and ACMV or SLCMV AC4 proteins, strongly disrupted plant development. This was most often seen as stunting of the plants and deformation of the stem, petioles, leaves, and flowers.

In the case of the CMV 2b protein, the strength of the altered phenotype in 2b-transgenic *Arabidopsis* plants corresponded with the severity of the symptoms induced by the strain from which the gene had been obtained. Transgenic expression of a 2b protein from a severe strain strongly inhibited growth of primary roots while both mild and severe strain 2b proteins enhanced the elongation of lateral roots. Overall, the effects of severe strain 2b proteins expressed as transgenes mimicked the phenotypes resulting from mutations in genes regulating the auxin response pathway and in *ago1* mutant plants.

Viral Suppression of the miRNA Pathway

It has been assumed that silencing suppressors alter plant development because they target elements that are common to, or highly similar between, the antiviral siRNA pathway and miRNA-directed regulation of host mRNA accumulation and translation (**Figure 1**). Since miRNAs negatively regulate the mRNA levels of several factors with roles in development (e.g., scarecrow-like factors, auxin response factors etc.), silencing suppressors which have the ability to interfere with components of small RNA-directed pathways can trigger or inhibit aspects of plant development.

Northern analysis has been used to study changes in the levels of miRNAs and target mRNAs accumulation in transgenic *Arabidopsis* plants expressing viral silencing suppressors. This method of analysis has provided evidence that some viral silencing suppressors disrupt of miRNA-regulated gene expression. The technique has also been used to monitor of levels of longer dsRNA species, miRNA precursor transcripts, miRNA duplexes, as well as the mRNA targets and their breakdown products (**Figure 1**). In combination with *in vivo* or *in vitro* studies of RNA or protein binding by silencing suppressor proteins, comparisons of steady-state levels of these various RNA species in nontransgenic versus transgenic plants expressing the silencing suppressors have helped reveal the target(s) of silencing suppressors within the miRNA pathway.

Is interference with miRNA-regulated gene expression entirely due to a case of mistaken identity, in which silencing suppressors accidentally or incidentally inhibit common targets or similar steps within the miRNA and siRNA-directed pathways? In some cases, for example where the mode of action of a silencing suppressor is to bind dsRNAs in a relatively nonsize selective manner, such as the TCV CP or the aureusvirus P14 protein, there would be a greater potential for cross-inhibition between the two pathways. In cases where the silencing suppressor acts by size-selective RNA binding, or can bind selectively to protein components of the silencing pathways (e.g., binding only to specific members of the AGO or DCL protein families), there is the possibility that silencing suppressors discriminate between components of the two RNA silencing pathways (**Figure 1**). Speculatively, this ability to discriminate suggests the possibility that natural selection operates on the genes for silencing suppressor to produce factors that minimize damage to host plants, or produce developmental changes that in some way favor the replication, spread, or transmission of the virus.

A recent breakthrough in animal virus research revealed that HIV-1 infection suppresses the microRNA pathway in a manner that promotes HIV-1 infection, but it is not evident whether this phenomenon depends on a viral silencing suppressor protein. Knockdown of *Dicer* and *Drosha* in HIV-1 infected cells showed that these two RNAse III enzymes contribute to suppression of HIV-1 infection. Microarray experiments identified miRNAs that were upregulated or induced only in HIV-1 infected cells. miR-17/92 is a polycistronic miRNA cluster which is downregulated during HIV-1 replication. miR-17/92 cluster includes miR17–5p and miR20a which target the histone acetylase PCAF, a cofactor for Tat in HIV-1. Thus, the miRNAs do not target HIV-1 but cellular factors necessary for HIV-1 gene expression. Thus, HIV-1 suppression of miR-17/92 cluster ensures a necessary supply of PCAF for virus replication.

Glossary

Catalytic RNA RNA molecules that are able to catalyze, in a protein-free medium, specific reactions involving the formation or breakage of covalent bonds. In nature, these reactions are usually transesterifications (self-cleavage and ligation) affecting the catalytic RNA itself.
Hammerhead structure The conserved secondary/tertiary structure shared by the smallest class of natural ribozymes. Most have been found in one or both strands of certain viroid and viroid-like satellite RNAs where they mediate self-cleavage of multimeric intermediates arising from replication through a rolling-circle mechanism.
Ribozyme RNA motif responsible for the catalytic activity of certain RNA molecules. In nature, they are found embedded within catalytic RNAs.

Introduction

Viroids are the smallest known agents of infectious disease – small (246–401 nt), highly structured, circular, single-stranded RNAs that lack detectable messenger RNA activity. While viruses have been described as 'obligate parasites of the cell's translational system' and supply some or most of the genetic information required for their replication, viroids can be regarded as 'obligate parasites of the cell's transcriptional machinery'. Thus far, viroids are known to infect only plants.

The first viroid disease to be studied by plant pathologists was potato spindle tuber. In 1923, its infectious nature and ability to spread in the field led Schultz and Folsom to group potato spindle tuber disease with several other 'degeneration diseases' of potatoes. Nearly 50 years were to elapse before Diener's demonstration in 1971 that the molecular properties of its causal agent, potato spindle tuber viroid (PSTVd), were fundamentally different than those of conventional plant viruses.

Genome Structure

Efforts to understand how viroids replicate and cause disease without the assistance of any viroid-encoded polypeptides have prompted detailed analysis of their structure. Viroids possess rather unusual properties for single-stranded RNAs (e.g., a pronounced resistance to digestion by ribonuclease and a highly cooperative thermal denaturation profile), leading to an early realization that they might have an unusual higher-order structure.

To date, the complete sequences of 29 distinct viroid species plus a large number of sequence variants have

been determined (**Table 1**). All are single-stranded circular RNAs containing 246–401 unmodified nucleotides. Theoretical calculations and physicochemical studies indicate that PSTVd and related viroids assume a highly base-paired, rod-like conformation *in vitro* (**Figure 1**). Pairwise sequence comparisons suggest that the series of short double helices and small internal loops that comprise this so-called 'native' structure are organized into five domains whose boundaries are defined by sharp differences in sequence similarity.

The 'central domain' is the most highly conserved viroid domain and contains the site where multimeric PSTVd RNAs are cleaved and ligated to form circular progeny. The 'pathogenicity domain' contains one or more structural elements which modulate symptom expression, and the relatively small 'variable domain' exhibits the greatest sequence variability between otherwise closely related viroids. The two 'terminal domains' appear to play an important role in viroid replication and evolution. Although these five domains were first identified in PSTVd, apple scar skin viroid (ASSVd) and related viroids also contain a similar domain arrangement. Certain viroids such as *Columnea* latent viroid (CLVd), Australian grapevine viroid (AGVd), and *Coleus blumei* viroid 2 (CbVd 2) appear to be 'mosaic molecules' formed by exchange of domains between two or more viroids infecting the same cell. RNA rearrangement/recombination can also occur within individual domains, leading, in coconut cadang-cadang (CCCVd) and citrus exocortis (CEVd) viroids, to duplications of the right terminal domain plus part of the variable domain. This domain model is not shared by avocado sunblotch (ASBVd) and related viroids.

Much less is known about viroid tertiary structure, especially *in vivo* where these molecules almost certainly accumulate as ribonucleoprotein particles. UV-induced

Table 1 Classification of viroids of known nucleotide sequence

Family[a]	*Genus*[a]	*Name*	*Abbreviation*	*Nucleotides*[b]
Pospiviroidae	*Pospiviroid*	Chrysanthemum stunt	CSVd	354–356
		Citrus exocortis	CEVd	368–375 (463–467)
		Columnea latent	CLVd	370–373
		Iresine	IrVd	370
		Mexican papita	MPVd	359–360
		Potato spindle tuber	PSTVd	356–361 (341)
		Tomato apical stunt	TASVd	360–363
		Tomato chlorotic dwarf	TCDVd	360
		Tomato planta macho	TPMVd	359–360
	Cocadviroid	Citrus viroid IV	CVd-IV	284
		Coconut cadang-cadang	CCCVd	246–247 (287–301)
		Coconut tinangaja	CTiVd	254
		Hop latent	HLVd	256
	Hostuviroid	Hop stunt[c]	HSVd	294–303
	Apscaviroid	Apple dimple fruit	ADFVd	306,307
		Apple scar skin[d]	ASSVd	329–334
		Australian grapevine	AGVd	369
		Citrus bent leaf	CBLVd	315,318
		Citrus dwarfing	CDVd	294,297
		Grapevine yellow speckle 1	GVYSVd 1	366–368
		Grapevine yellow speckle 2[e]	GYSVd 2	363
		Pear blister canker	PBCVd	315,316
	Coleviroid	*Coleus blumei* 1	CbVd 1	248–251
		Coleus blumei 2	CbVd 2	301,302
		Coleus blumei 3	CbVd 3	361–364
Avsunviroidae	*Avsunviroid*	Avocado sunblotch	ASBVd	246–251
	Pelamoviroid	Chrysanthemum chlorotic mottle	CChMVd	398–401
		Peach latent mosaic	PLMVd	335–351
	Elaviroid	Eggplant latent	ELVd	332–335

[a]Classification follows scheme proposed by Flores *et al*. (see VIII Report of the International Committee on Taxonomy of Viruses) with minor modifications. The nucleotide sequences of blueberry mosaic, burdock stunt, *Nicotiana glutinosa* stunt, pigeon pea mosaic mottle, and tomato bunchy top viroids are currently unknown; consequently, these viroids have not been assigned to specific genera. Whether apple fruit crinkle and citrus viroid original source should be considered variants or new viroid species of genus *Apscaviroid* is pending.
[b]Sizes of variants containing insertions or deletions arising *in vivo* are shown in parentheses.
[c]Includes cucumber pale fruit, citrus cachexia, peach dapple, and plum dapple viroids.
[d]Includes pear rusty skin and dapple apple viroids.
[e]Formerly termed grapevine viroid 1B.

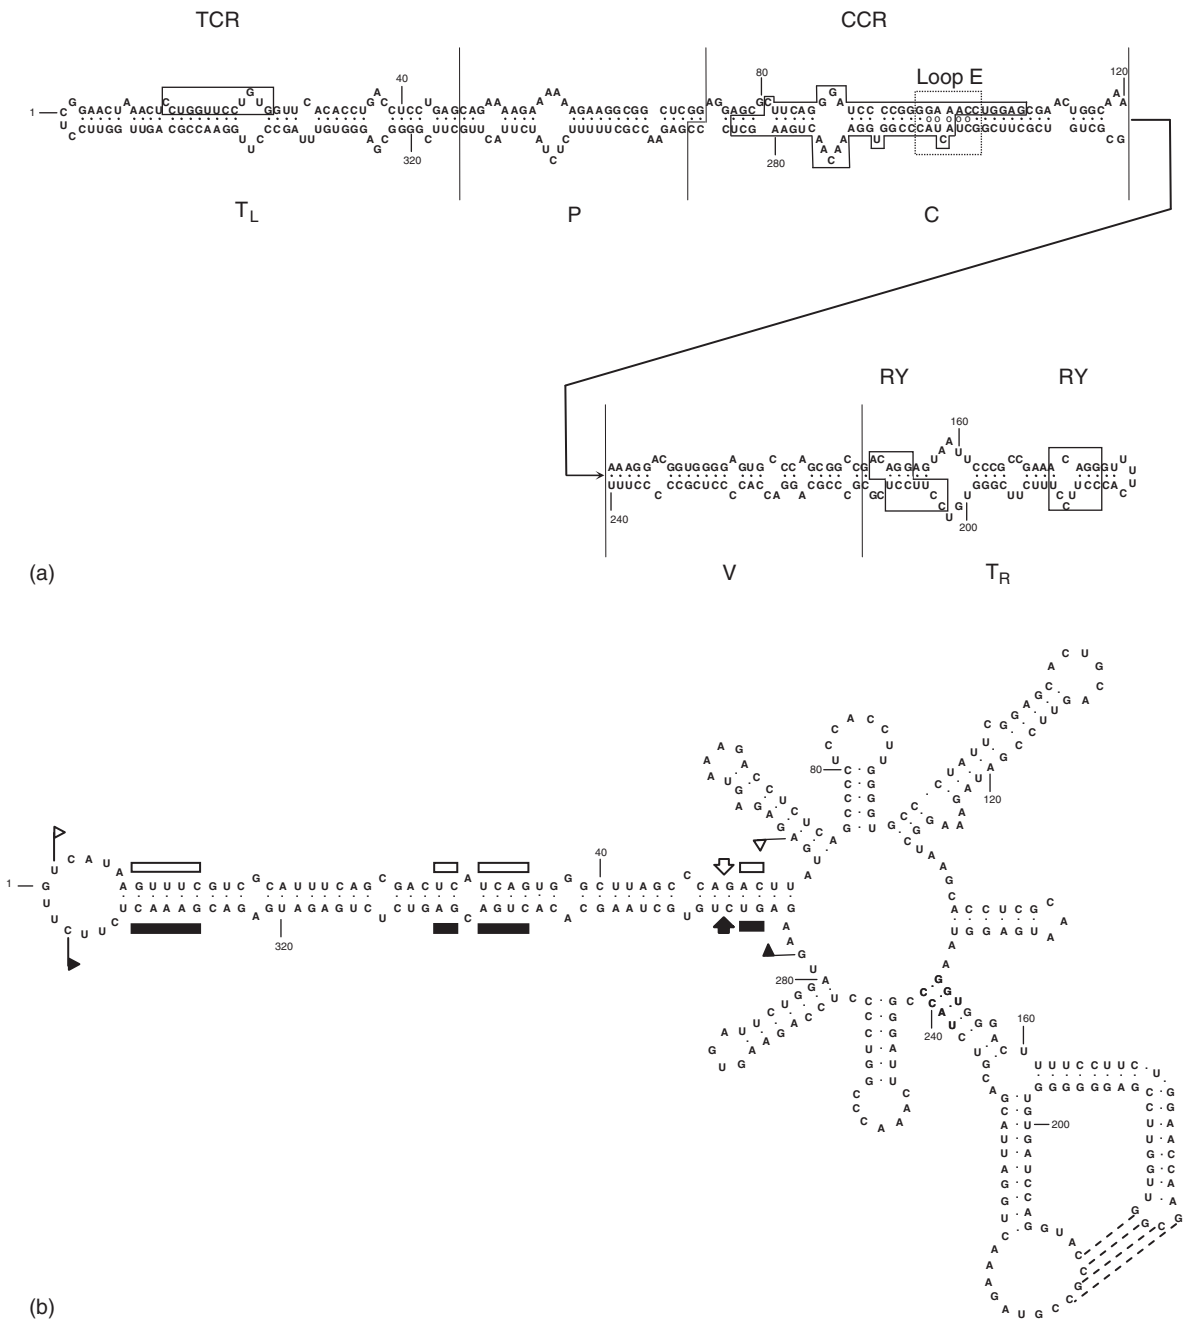

Figure 1 (a) The rod-like secondary structure of PSTVd (intermediate strain) showing the five domains characteristic of members of the family *Pospiviroidae:* the terminal left (T_L), pathogenicity (P), central (C), variable (V), and terminal right (T_R). The central conserved region (CCR) is located within the C domain and contains a UV-sensitive loop E motif with noncanonical base pairs (denoted by circles). The T_L domains of genera *Pospiviroid* and *Apscaviroid* contain a terminal conserved region (TCR), while those of genera *Hostuviroid* and *Cocadviroid* contain a terminal conserved hairpin (not shown). The T_R may also contain 1–2 copies of a protein-binding RY motif. (b) The branched secondary structure of PLMVd (reference variant). Plus and minus self-cleavage domains are indicated by flags, nucleotides conserved in most natural hammerhead structures by bars, and the self-cleavage sites by arrows. Black and white symbols refer to plus and minus polarities, respectively. Nucleotides involved in a pseudoknot are indicated by broken lines. Redrawn with modifications from Gross HJ, Domdey H, Lossow C, *et al*. (1978) Nucleotide sequence and secondary structure of potato spindle tuber viroid. *Nature* 273: 203–208; Hernández C and Flores R (1992) Plus and minus RNAs of peach latent mosaic viroid self-cleave *in vitro* through hammerhead structures. *Proceedings of the National Academy of Sciences, USA* 89: 3711–3715; Bussière F, Ouellet J, Côté F, Lévesque D, and Perreault JP (2000) Mapping in solution shows the peach latent mosaic viroid to possess a new pseudoknot in a complex, branched secondary structure. *Journal of Virology* 74: 2647–2654.

cross-linking of two nucleotides within a loop E motif in the central domain of PSTVd provided the first definitive evidence for such tertiary interactions. Similar UV-sensitive structural elements have also been discovered in a number of other RNAs including 5S eukaryotic rRNA, adenovirus VAI RNA, and the viroid-like domain of the hepatitis delta virus genome. Loop E forms during the conversion of multimeric PSTVd RNAs into monomers. The ability of ASBVd-related RNAs to undergo spontaneous self-cleavage mediated by hammerhead ribozymes as well as the presence of pseudoknots critical for infectivity in some other members of the *Avsunviroidae* (**Figure 1**) provide additional evidence for the functional importance of viroid tertiary structure.

Classification

Based upon differences in the structural and functional properties of their genomes, viroids species are assigned to one of two taxonomic families (see **Table 1**). Members of the family *Pospiviroidae* (type member PSTVd) have a rod-like secondary structure that contains five structural–functional domains and several conserved motifs. Most members of the family *Avsunviroidae* (type member ASBVd), in contrast, appear to adopt a branched conformation, and multimeric RNAs of all family members behave as catalytic RNAs and undergo spontaneous self-cleavage (**Figure 1**). Differences in their sites of replication also support this classification scheme; that is, PSTVd and ASBVd replicate in the nucleus and the chloroplast, respectively, and the same appears to occur for other members of each family. Each family is subdivided into genera according to certain demarcating criteria. Groups of sequence variants that show >90% sequence identity in pairwise comparisons and share some common biological property are arbitrarily defined as viroid species. *In vivo*, each viroid species is actually a 'quasispecies', that is, a collection of closely related sequences subject to a continuous process of variation, competition, and selection. There is phylogenetic evidence for an evolutionary link between viroids and other viroid-like subviral RNAs (**Figure 2**).

Host Range and Transmission

All viroids are mechanically transmissible, and most are naturally transmitted from plant to plant by man and his tools. Individual viroids vary greatly in their ability to infect different plant species. PSTVd can replicate in about 160 primarily solanaceous hosts, while only two members of the family Lauraceae are known to support ASBVd replication. HSVd has a particularly wide host range that includes herbaceous species as well as woody perennials. Many natural hosts are either vegetatively propagated or crops that are subjected to repeated grafting or pruning operations. PSTVd, ASBVd, and CbVd1 are vertically transmitted through pollen and/or true seed, but the significance of this mode of transmission in the natural spread of disease is unclear. PSTVd can be encapsidated by the coat protein of potato leafroll virus (PLRV, a polerovirus) as well as velvet tobacco mottle virus (VTMoV, a sobemovirus), and epidemiological surveys suggest that PLRV facilitates viroid spread under field conditions.

Commonly used techniques for the experimental transmission of viroids include the standard leaf abrasion methods developed for conventional viruses, 'razor slashing' methods in which phloem tissue in the stem or petiole is inoculated via cuts made with a razor blade previously dipped into the inoculum, and, in the case of CCCVd, high-pressure injection into folded apical leaves. Viroids can also be transmitted by either plant transformation or 'agroinoculation' during which a modified *Agrobacterium tumefaciens* Ti plasmid is used to introduce full-length viroid-complementary DNA into the potential host cell. Either technique can overcome the marked resistance of some hosts to mechanical inoculation. Identification of the molecular mechanism(s) that determine viroid host range remains an important research goal.

Symptomatology

Viroids and conventional plant viruses induce a very similar range of macroscopic symptoms. Symptom expression is usually optimal at the same relatively high temperatures (30–33 °C) that promote viroid replication. Stunting and leaf epinasty (a downward curling of the leaf lamina resulting from unbalanced growth within the various cell layers) are considered the classic symptoms of viroid infection. Other commonly observed symptoms include vein clearing, veinal discoloration or necrosis, and the appearance of localized chlorotic/necrotic spots or mottling in the foliage. Symptoms may also be expressed in flowers and bark, and fruits or tubers from viroid-infected plants may be abnormally shaped or discolored. Viroid infection of certain citrus rootstock/scion combinations may result in tree dwarfing (**Figure 3**). Viroid infections are often latent and rarely kill the host.

Viroid infections are also accompanied by a number of cytopathic effects – chloroplast and cell wall abnormalities, the formation of membranous structures in the cytoplasm, and the accumulation of electron-dense deposits in both chloroplasts and cytoplasm. Metabolic changes include dramatic alterations in growth regulator levels.

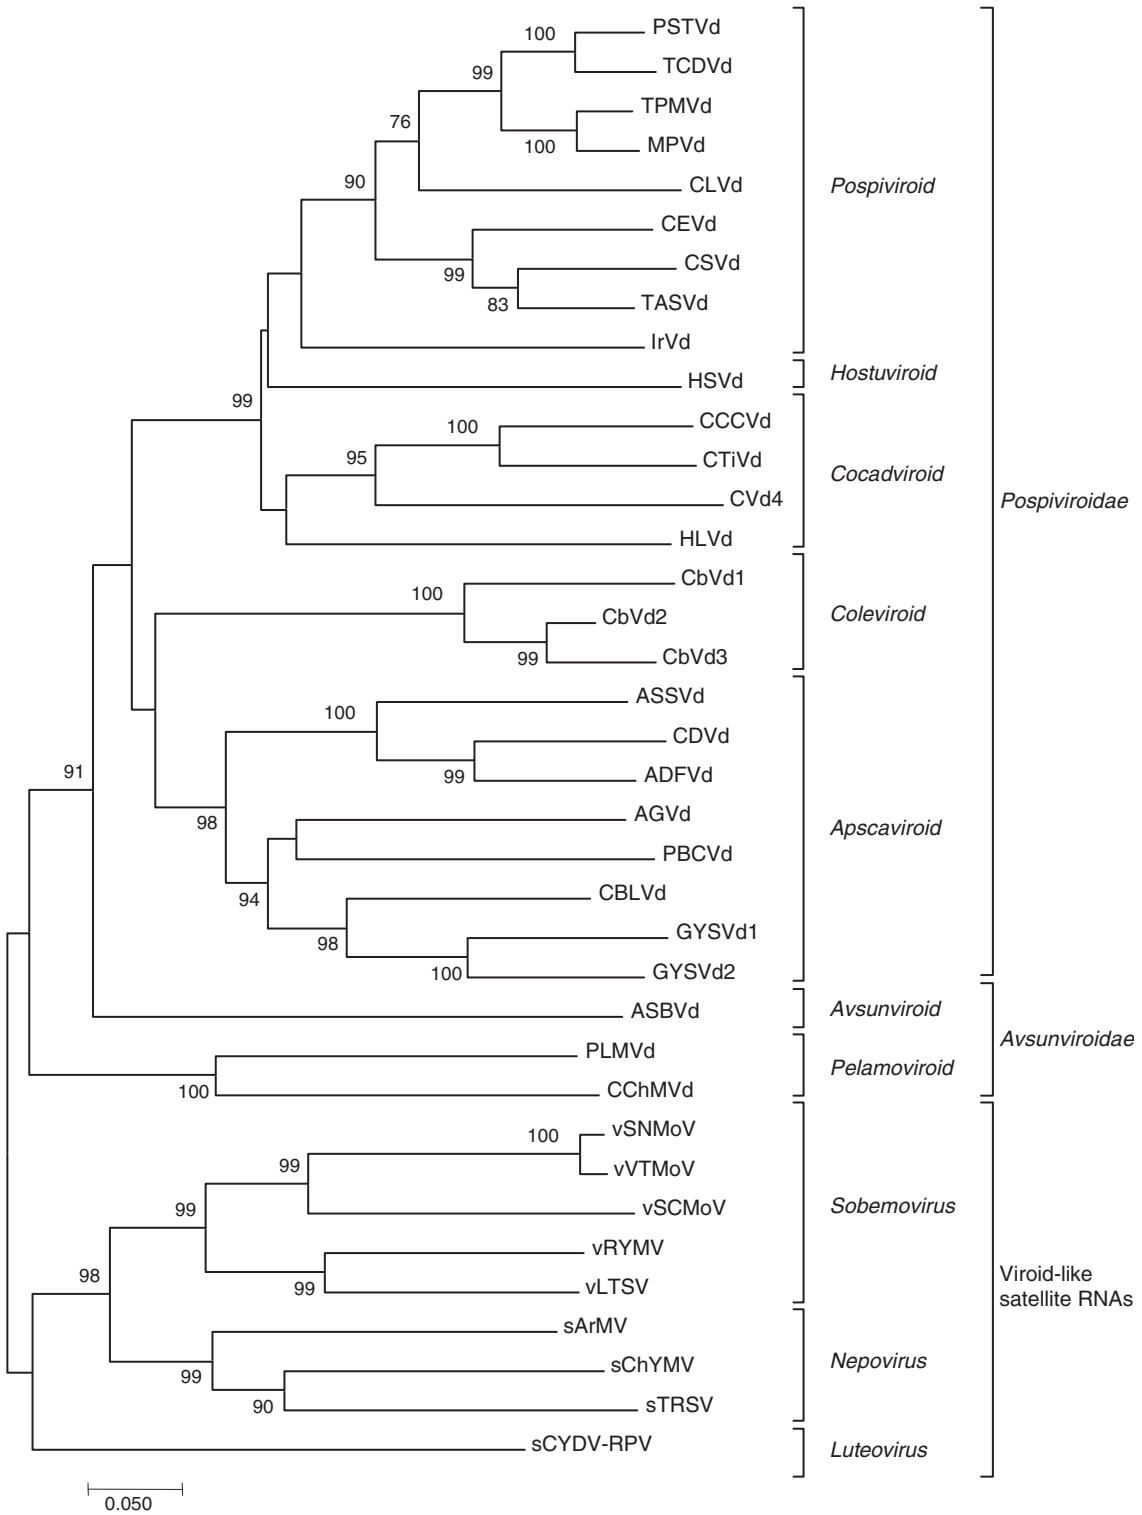

Figure 2 Neighbor-joining phylogenetic tree obtained from an alignment manually adjusted to take into account local similarities, insertions/deletions, and duplications/rearrangements described in the literature for viroid and viroid-like satellite RNAs. Bootstrap values were based on 1000 random replicates (only values >70% are shown). Viroid abbreviations are those used in **Table 1**. Viroid-like satellite RNAs: lucerne transient streak virus (sLTSV); rice yellow mottle virus (sRYMV); subterranean clover mottle virus (sSCMoV); *Solanum nodiflorum* mottle virus (sSNMoV)); velvet tobacco mottle virus (sVTMoV); tobacco ringspot virus (sTRSV); *Arabis* mosaic virus (sArMV); chicory yellow mottle virus (sChYMV); cereal yellow dwarf virus-RPV (sCYDV-RPV). Adapted from Elena SF, Dopazo J, de la Peña M, Flores R, Diener TO, and Moya A (2001) Phylogenetic analysis of viroid and viroid-like satellite RNAs from plants: A reassessment. *Journal of Molecular Evolution* 53: 155–159.

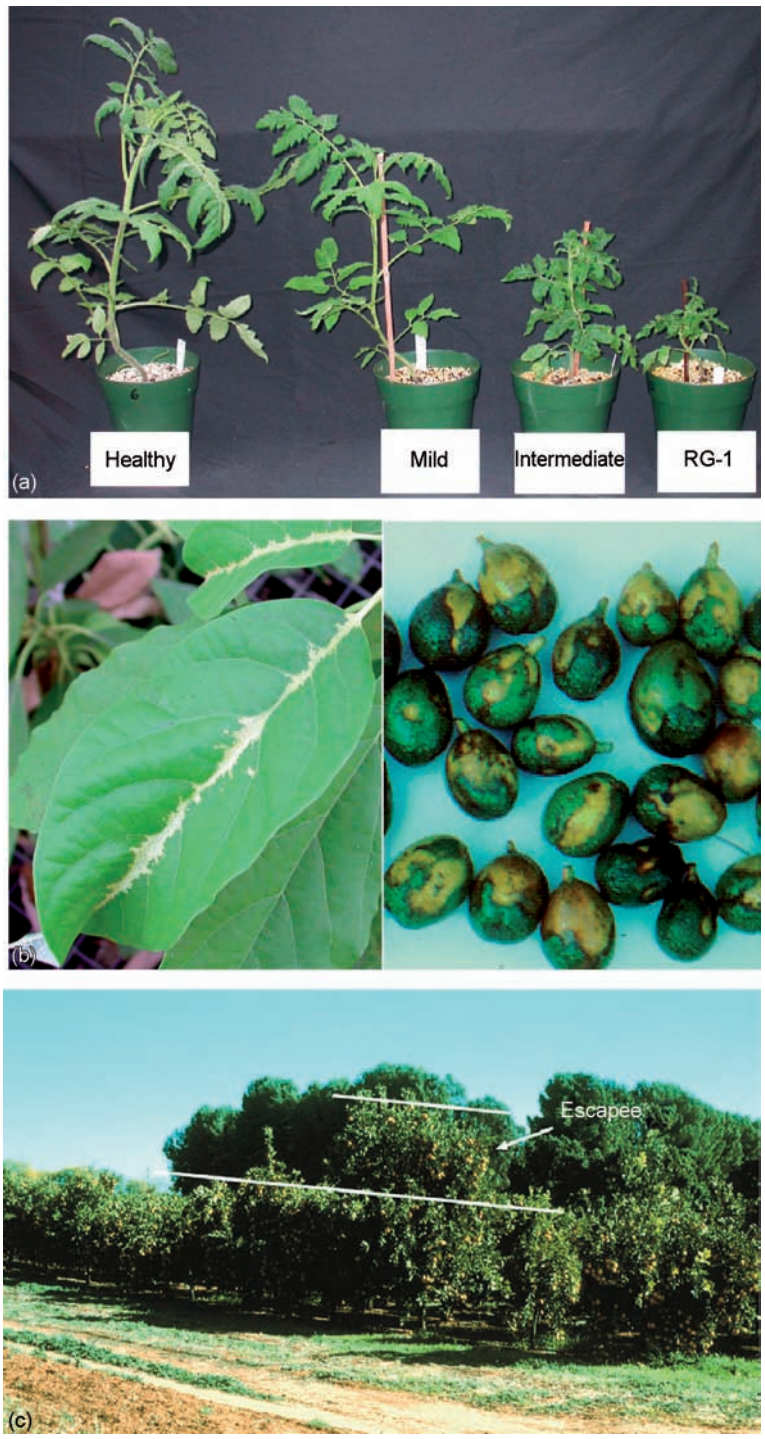

Figure 3 (a) Symptoms of PSTVd infection in Rutgers tomato approximately 4 weeks after inoculation of cotyledons with PSTVd strains causing mild, intermediate, and severe symptoms. (b) Symptoms of ASBVd infection in avocado fruits and leaves. (c) Viroid-induced dwarfing of citrus growing on susceptible rootstocks: All trees in the block were graft-inoculated with CDVd shortly after transfer to the field; only one tree (right foreground) escaped infection. Note the difference in height.

Geographic Distribution

Although PSTVd, HSVd, CEVd, and ASBVd are widely distributed throughout the world, other viroids have never been detected outside the areas where they were first reported. Several factors may contribute to this variation in distribution pattern. Among the crops most affected by viroid diseases are a number of valuable woody perennials such as grapes, citrus, various pome and stone fruits, and hops. Propagation and distribution of improved cultivars is

highly commercialized, with the result that many cultivars are now grown worldwide. The international exchange of plant germplasm also continues to increase at a rapid rate. In both instances, the large number of latent (asymptomatic) hosts facilitates viroid spread.

Epidemiology and Control

Viroid diseases pose a potential threat to agriculture, and several are of considerable economic importance. Ready transmission of PSTVd by vegetative propagation, foliar contact, and true seed or pollen continues to pose a serious threat to potato germplasm collections and breeding programs. Coconut cadang-cadang has killed over 30 million palms in the Philippines since it was first recognized in the early 1930s. While many viroids were first detected in ornamental or crop plants, most viroid diseases are thought to result from chance transfer from endemically infected wild species to susceptible cultivars. Several lines of circumstantial evidence are consistent with this hypothesis:

1. The experimental host ranges of several viroids include many wild species, and these wild species often tolerate viroid replication without the appearance of recognizable disease symptoms.
2. Although co-evolution of host and pathogen is often accompanied by appearance of gene-for-gene vertical resistance, no useful sources of resistance to PSTVd infection have been identified in the cultivated potato.
3. Viroids and/or viroid-related RNAs closely related to TPMVd and CCCVd have been detected in weeds and other wild vegetation growing near fields containing viroid-infected plants.

Growers and plant pathologists are unlikely to have simply overlooked diseases with symptoms as severe as those of chrysanthemum stunt or cucumber pale fruit, two diseases first reported after World War II. Large-scale monoculture of genetically identical crops and the commercial propagation/distribution of many cultivars are two comparatively modern developments which would facilitate the development of serious disease problems following the chance transfer of viroids from wild hosts to cultivated plants. Viroid diseases may also arise by transfer between cultivated crop species. For example, pears provide a latent reservoir for ASSVd; likewise, while HSVd infections of grapes are often symptomless, this viroid causes severe disease in hops. In both instances, the two crops are often grown in close proximity.

Because no useful sources of natural resistance to viroid disease are known, diagnostic tests continue to play a key role in efforts to control viroid diseases. Since viroids lack a protein capsid, the antibody-based techniques used to detect many plant viruses are not applicable. Tests based upon their unique molecular properties have largely supplanted biological assays for viroid detection. Problems with viroid bioassays include the length of time required for completion (weeks to years) and difficulties in detecting mild or latent strains. Several rapid (1–2 day) protocols involving polyacrylamide gel electrophoresis (PAGE) under denaturing conditions take advantage of the circular nature of viroids. Using these protocols, nanogram amounts of viroid can be unambiguously detected without the use of radioactive isotopes. In recent years, diagnostic procedures based upon nucleic acid hybridization or the polymerase chain reaction (PCR) are being widely used. The simplest methods involve the hybridization of a nonradioactively labeled viroid-complementary DNA or RNA probe to viroid samples that have been bound to a solid support followed by colorimetric or chemiluminescent detection of the resulting DNA–RNA or RNA–RNA hybrids. Such conventional 'dot blot' assays can detect picogram amounts of viroids using clarified plant sap or tissue prints rather than purified nucleic acid as the viroid source. PCR-based protocols are finding increasing acceptance in those cases where either this level of sensitivity is inadequate or a number of closely related viroids are present in the same sample.

Molecular Biology

Although devoid of messenger RNA activity, viroids replicate autonomously and cause disease in a wide variety of plants. Much has been learned about the molecular biology of viroids and viroid–host interaction over the past 25 years, but the precise nature of the molecular signals involved remains elusive. A series of questions first posed by Diener summarizes the many gaps in our current understanding of the biological properties of these unusual molecules:

1. What molecular signals do viroids possess (and cellular RNAs evidently lack) that induce certain DNA-dependent RNA polymerases to accept them as templates for the synthesis of complementary RNA molecules?
2. What are the molecular mechanisms responsible for viroid replication? Are these mechanisms operative in uninfected cells? If so, what are their functions?
3. How do viroids induce disease? In the absence of viroid-specified proteins, disease must arise from direct interaction(s) of viroids (or viroid-derived RNA molecules) with host-cell constituents. Infections by PSTVd and ASBVd induce RNA silencing (see below).
4. What determines viroid host range? Are viroids restricted to higher plants, or do they have counterparts in animals?
5. How did viroids originate?

Replication

A variety of multimeric plus- and minus-strand RNAs have been detected by nucleic acid hybridization in viroid-infected tissues. Based on their analysis, viroid replication has been proposed to proceed via a 'rolling circle' mechanism that involves reiterative transcription of the incoming plus circular RNA to produce a minus-strand RNA template. ASBVd and related viroids utilize a symmetric replication cycle in which the multimeric minus strand is cleaved to unit-length molecules and circularized before serving as template for the synthesis of multimeric plus strands. PSTVd and related viroids utilize an asymmetric cycle in which the multimeric minus strand is directly transcribed into multimeric plus strands. In both cases, the multimeric plus strands are cleaved to unit-length molecules and circularized.

A diversity of host-encoded enzymes have been implicated in viroid replication. Low concentrations of α-amanitin specifically inhibit the synthesis of both PSTVd plus and minus strands in nuclei isolated from infected tomato, strongly suggesting the involvement of DNA-dependent RNA polymerase II, transcribing an RNA template, in the replication of PSTVd and related viroids. In nuclear extracts, transcription of the PSTV plus strand by RNA polymerase II starts in the left terminal loop; furthermore, incubation of active replication complexes containing CEVd with a monoclonal antibody directed against the carboxy-terminal domain of RNA polymerase II results in the immunoprecipitation of both CEVd plus- and minus-strand RNAs. Mature PSTVd plus strands accumulate in the nucleolus and the nucleoplasm, while *in situ* hybridization indicates that minus-strand RNAs are confined to the nucleoplasm. The identity of the polymerase(s) responsible for replication of members of the family *Avsunviroidae* in the chloroplast is less certain. ASBVd synthesis is resistant to tagetitoxin, strongly indicating the involvement of a nuclear-encoded chloroplastic RNA polymerase. Initiation sites for both ASBVd plus- and minus-strand synthesis have been mapped to the AU-rich terminal loops of their respective native structures.

In vitro evidence indicates that specific cleavage of multimeric PSTVd plus-strand RNAs requires (1) rearrangement of the conserved central region to form a branched structure containing a GNRA tetraloop and (2) the action of one or more host-encoded nucleases. Other less-efficient processing sites can also be used *in vivo*. Plus- and minus-strand RNAs of ASBVd and related viroids, in contrast, undergo spontaneous self-cleavage through hammerhead ribozymes to form linear monomers (**Figure 4**). Addition of certain chloroplast proteins acting as RNA chaperones facilitates this hammerhead ribozyme-mediated self-cleavage reaction. The final step in viroid replication is the ligation of linear monomers to form mature circular progeny. Plant cells are known to contain RNA ligase activities which can act upon the 5′ hydroxyl and 2′,3′ cyclic phosphate termini formed by either cleavage pathway.

Movement

Upon entering a potential host cell, viroids must move to either the nucleus (*Pospiviroidae*) or chloroplast (*Avsunviroidae*) before beginning replication. Available data suggest that PSTVd enters the nucleus as a ribonucleoprotein complex formed by the interaction of cellular proteins with specific viroid sequence or structural motifs. VirP1, a bromodomain-containing protein isolated from tomato, has a nuclear localization signal and binds to the terminal right domain of PSTVd. Proteins such as TFIIIA and ribosomal protein L5 that bind to the loop E motif may also be involved in viroid transport into the nucleus. How ASBVd or other members of the family *Avsunviroidae* enter and exit the chloroplast is currently unknown.

To establish a systemic infection, viroids leave the initially infected cell – moving first from cell to cell and then long distances through the host vasculature. Upon injection into symplasmically isolated guard cell in a mature tomato leaf, fluorescently labeled PSTVd RNA does not move. Injection into interconnected mesophyll cells, in contrast, is followed by rapid cell-to-cell movement through the plasmodesmata. Long-distance movement of viroids, like that of nearly all plant viruses, occurs in the phloem where it follows the typical source-to-sink pattern of photoassimilate transport. Viroid movement in the phloem almost certainly requires formation of a ribonucleoprotein complex, possibly involving a dimeric lectin known as phloem protein 2 (PP2), the most abundant protein in phloem exudate. Movement of PSTVd in the phloem appears to be sustained by replication in supporting cells and is tightly regulated by developmental and cellular factors. For example, *in situ* hybridization reveals the presence of PSTVd in vascular tissues underlying the shoot apical meristem of infected tomato, but entry into the shoot apical meristem itself appears to be blocked. Another important control point for PSTVd trafficking is the bundle sheath–mesophyll boundary in the leaf. By disrupting normal pattern of viroid movement, it may be possible to create a plant that is resistant/immune to viroid infection.

Pathogenicity

Sequence comparisons of naturally occurring PSTVd and CEVd variants as well as infectivity studies with chimeric viroids, constructed by exchanging the pathogenicity domains of mild and severe strains of CEVd, have clearly shown that the pathogenicity domain in the family *Pospiviroidae* contains important determinants of symptom expression. Symptom expression is also affected by the

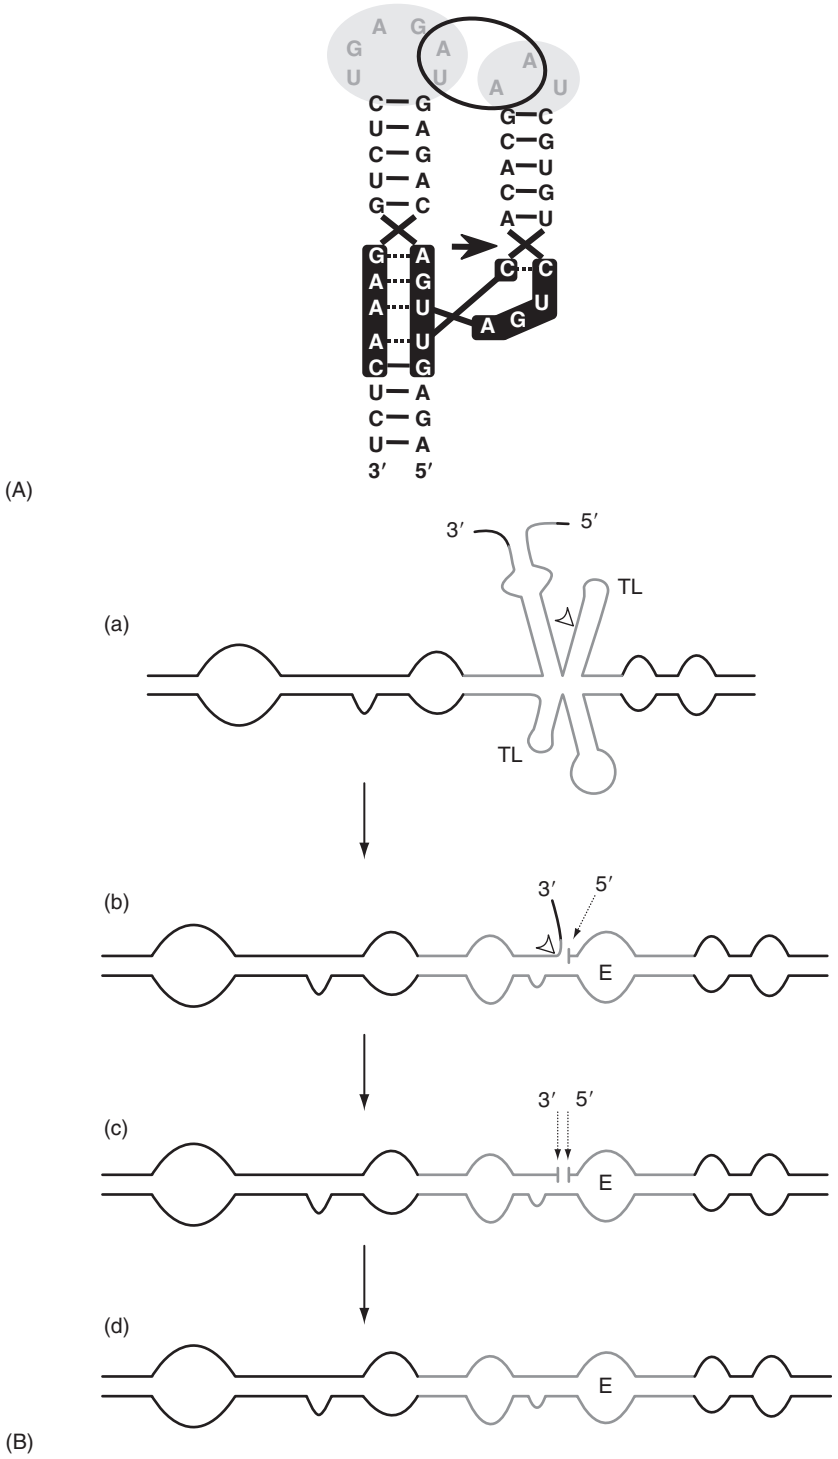

Figure 4 Cleavage of multimeric viroid RNAs requires rearrangement of the native structure. (A) During transcription, the strands of both polarities of members of the family *Avsunviroidae* can fold into hammerhead structures (here illustrated for the hammerhead of the PLMVd plus RNA) and self-cleave accordingly. Nucleotides conserved in most natural hammerhead structures are on a black background, and the self-cleavage site is denoted by an arrow. A circle delimits the presumed tertiary interaction between terminal loops enhancing the catalytic activity. Watson-Crick and noncanonical base pairs are represented by continuous and discontinuous lines, respectively. After self-cleavage, the RNA adopts a new conformation favoring ligation (or self-ligation). (B) Processing of a longer-than-unit-length plus PSTVd RNA transcript in a potato nuclear extract. The central conserved region of the substrate for the first cleavage reaction (a) contains a tetraloop (denoted TL). After dissociation of the 5′ segment from the cleavage site, the new 5′ end refolds and is stabilized by formation of a UV-sensitive loop E (b), while the 3′ end partially base-pairs with the lower strand. Single-stranded nucleotides at the 3′ end are then cleaved between positions 95 and 96 (c), and ligation of the 5′ and 3′ termini (d) results in formation of mature circular progeny. From Baumstark T, Schröder ARW, and Riesner D (1997) Viroid processing: Switch from cleavage to ligation is driven by a change from a tetraloop to a loop E conformation. *EMBO Journal* 16: 599–610.

rate of viroid replication, and sequence changes in the variable domain have been shown to regulate progeny titers in infected plants. Studies with TASVd revealed the presence of a third pathogenicity determinant in the left terminal loop. Also, a single U/A change position 257 in the central domain of PSTVd results in the appearance of severe stunting and a 'flat top' phenotype. In the family *Avsunviroidae,* determinants of pathogenicity have been mapped to either a tetraloop capping a hairpin stem in chrysanthemum chlorotic mottle viroid (CChMVd) or an insertion that folds into a hairpin also capped by a tetraloop in peach latent mosaic viroid (PLMVd).

The ability of novel viroid chimeras to replicate and move normally from cell to cell implies certain basic similarities between their structures *in vitro* and *in vivo* but provides no information about the nature of the molecular interactions responsible for symptom development. Until recently, it was widely assumed that the mature viroid RNA was the direct pathogenic effector. Just like viruses, however, viroid replication is also accompanied by the production of a variety of small (21–26 nt) RNA molecules. The role of these small interfering RNAs (siRNAs) in viroid pathogenicity is not yet clear, but the inverse relationship between accumulation levels of the mature viroid RNAs and the corresponding siRNAs for members of the family *Avsunviroidae* suggest that the latter may regulate the titer of the former. Also, recovery of tomato plants from the symptoms of severe PSTVd infections is preceded by the accumulation of PSTVd-specific siRNA.

Viroid infections are accompanied by quantitative changes in a variety of host-encoded proteins. Certain of these are 'pathogenesis-related' proteins whose synthesis or activation is part of a general host reaction to biotic or abiotic stress, but others appear to be more specific. In tobacco, PSTVd infection results in the preferential phosphorylation of a host-encoded 68 kDa protein that is immunologically related to an interferon-inducible, dsRNA-dependent mammalian protein kinase of similar size. The human kinase is differentially activated by PSTVd strains of varying pathogenicity *in vitro*, while infection of tomato by intermediate or severe strains of PSTVd induces the synthesis of PKV, a dual-specificity, serine/threonine protein kinase. Broad changes in host gene expression following PSTVd infection have been detected by complementary DNA macroarray analysis.

Host Range

Possibly as a result of its involvement in the cleavage/ligation of progeny RNA, nucleotides in the central domain of PSTVd and related viroids appear to play an important role in determining host range. For example, a single nucleotide substitution in the loop E motif results in a dramatic increase in the rate of PSTVd replication in tobacco. The biological properties of CLVd also suggest that this domain contains one or more host-range determinants. CLVd appears to be a natural mosaic of sequences present in other viroids; phylogenetic analysis (see **Figure 2**) suggests that it can be considered to be a PSTVd-related viroid whose conserved central domain has been replaced by that of HSVd. Like HSVd (but not PSTVd or related viroids), CLVd can replicate and cause disease in cucumber.

Origin and Evolution

Much of the early speculation about viroid origin involved their possible origin as 'escaped introns' (i.e., descent from normal host RNAs). More recently, however, viroids have been proposed to represent 'living fossils' of a precellular RNA world that assumed an intracellular mode of existence sometime after the evolution of cellular organisms. The presence of ribozymes in members of the *Avsunviroidae* strongly supports this view.

The inherent stability of viroids and viroid-like satellite RNAs (structurally similar to viroids but functionally dependent on helper viruses) which arises from their small size and circularity would have enhanced the probability of their survival in primitive, error-prone RNA self-replicating systems and assured their complete replication without the need for initiation or termination signals. Most viroids (but not satellite RNAs or random sequences of the same base composition) also display structural periodicities with repeat units of 12, 60, or 80 nt. The high error rate of prebiotic replication systems may have favored the evolution of polyploid genomes, and the mechanism of viroid replication (i.e., rolling-circle transcription of a circular template) provides an effective means of genome duplication.

Viroids and viroid-like satellite RNAs all possess efficient mechanisms for the precise cleavage of their oligomeric replication intermediates to form monomeric progeny. PSTVd and related viroids appear to require proteinaceous host factor(s) for cleavage, but others (members of the family *Avsunviroidae* and viroid-like satellite RNAs) contain ribozymes far smaller and simpler than those derived from introns. Thus, ASBVd and the other self-cleaving viroids may represent an evolutionary link between viroids and viroid-like satellite RNAs. No viroid is known to code for protein, a fact that is consistent with the possibility that viroids are phylogenetically older than introns.

Phylogenetic evidence for an evolutionary link between viroids and other viroid-like subviral RNAs has been presented by Elena *et al.* (see **Figure 2**). Among several subviral RNAs possibly related to viroids is carnation small viroid-like RNA, a 275 nt circular molecule with self-cleaving hammerhead structures in both its plus and minus strands that has a DNA counterpart. This novel retroviroid-like element shares certain features with both viroids and a small RNA transcript from newt.

Glossary

Demarcation A mapping of ranges of pairwise distances into taxonomic categories.

classification method that has drawn more and more attention from virologists is pairwise sequence comparison (PASC). In this article, we briefly describe various sequence comparison methods, introduce the PASC tool, and compare it with other methods.

Introduction

Virus classification is very important for virus research. It is also an extremely difficult task for many virus families. Traditionally, virus classification relied on properties such as virion morphology, genome organization, replication mechanism, serology, natural host range, mode of transmission, and pathogenicity. Yet viruses sharing the above properties can reveal tremendous differences at the genome level. For example, classification of many phages is currently based on presence, structure, and length of a tail, and this approach has been shown not to correlate with genomic information, leading to a very difficult situation and hundreds of unclassified phages.

Molecular virus classification based on virus sequences has been used increasingly in recent years, thanks to the growing number of viral sequences available in the public sequence databases. The most commonly used sequence comparison methods include multiple sequence alignment and phylogenetic analysis. Another molecular

Sequence Comparison Methods

A universal approach to compare biological sequences, in a sense of producing meaningful results at various levels of divergence, is in the realm of sequence alignment. An alignment is an arrangement of residues of two or more sequences in a way that reveals their possible relatedness, with space characters inserted into the sequences to indicate single-residue insertions and deletions. A variety of algorithms and programs are available to suit a wide range of problems requiring sequence alignments as parts of their solutions. Depending on the specifics of a problem, different types of algorithms or their combinations may work best. Most alignment algorithms can be broadly categorized by the scope of their application on sequences (local vs. global), or by the number of sequences involved (pairwise vs. multiple).

Each pairwise alignment can be viewed as an array of per-residue operations transforming one sequence to the other. These operations are substitutions (called matches

and mismatches in nucleotide alignments), insertions, and deletions. A generalization of this concept to multiple alignments is possible. Alignments are scored using a scoring scheme appropriate for a biological context. The widely used affine scheme assigns substitution scores to substitutions and a penalty to each space, and an additional penalty to each gap defined as a maximal consecutive run of spaces. Given a set of sequences, an alignment is called optimal if it has the maximal score over all possible alignments. Optimal alignments are not necessarily unique; two or more alignments can be tied with the same score.

Local algorithms are capable of detecting similarities between arbitrary parts of sequences. Applications involving local alignments are numerous, including search for orthologous genes or conserved protein domains. Alignments produced with local algorithms are tractable to mathematical analysis, which allowed the building of tools that evaluate statistical significance of the alignments. The algorithm for computing optimal local alignments is known as Smith–Waterman and it runs in time proportional to the product of the sequences' lengths. Since this is too slow for large-scale searches, many heuristic methods (with BLAST being the most popular) have been developed, allowing matching typical queries against gigabase-sized archives of sequence in a matter of seconds.

Fast as they are, algorithms like BLAST are not suitable for all applications. Although they are capable of picking out segments of high similarity, no segment of input sequences is guaranteed to be a part of the resulting alignments, and some segments may belong to more than one individual alignment. Additional post-processing steps are often required in order to produce consistent sets of local alignments. This complicates the use of local alignments in applications involving uniform computing of identities.

When sequences in the set are expected to align end-to-end, global alignment algorithms are applicable. The strict algorithm for computing an optimal global alignment is known as Needleman–Wunsch. With the running time estimate being the same as in the Smith–Waterman, global alignments allow straightforward evaluation of identities as they provide unambiguous mapping for every residue. An important end-space free variant is used when one of the sequences is expected to align in the interior of another. Global algorithms are normally not suitable for applications aiming to capture rearrangement events.

Multiple sequence alignments can technically be viewed as a generalization of the pairwise case. However, they often serve different goals, such as a detection of weak and/or dispersed similarities over a set of sequences known to share a common function or structure. Computing an optimal multiple sequence alignment is a computationally costly task, and most implementations use various heuristics to approximate the alignment in a reasonable time. Note that even when the optimal multiple alignment is available, pairwise alignments inferred from it are not guaranteed to be optimal. There are many multiple sequence alignment tools available: CLUSTALW, DIALIGN, MAFFT, MUSCLE, PROBCONS, ProDA, and T-COFFEE, etc.

Phylogenetic analysis is probably the most frequently used molecular virus classification tool. A phylogeny or evolutionary tree is a mathematical structure which is used to model the historical relationships between groups of organisms or sequences. Main types of methods used to construct phylogenetic trees include distance-based methods (such as neighbor-joining), parsimony, maximum likelihood, and other probabilistic inference techniques. The most common distance-based methods utilize multiple sequence alignments to estimate the evolutionary distance between each pair of sequences and reconstruct the tree from the distances. Either protein sequences or DNA sequences can be used.

Phylogenetic analysis was used in the vast majority of virus families described in the Eighth Report of the International Committee on the Taxonomy of Viruses (ICTV) to support their classification. It has also been applied to the classification of a large group of distantly related viruses. For example, phages consist of many different families. Therefore, the conventional phylogenetic analysis that uses genomic sequences or individual protein sequences would not work for the classification of phages as a whole group. A 'phage proteomic tree' was developed to classify phages by the overall similarities of all protein sequences present in the phage genomes.

Although phylogenetic analysis is well established as a tool for virus classification, it is usually computationally intensive, and requires expertise to perform the analysis and to interpret the results. A more robust method is preferred so that researchers without an advanced computer system and advanced knowledge about the phylogenetic analysis can also use it. Also, as discussed below, despite the fact that some of the sequence alignment methods (such as BLAST) are very fast and easy to carry out, their results will not reveal the taxonomic relationships between the two viruses. A method that can place a new virus in the appropriated taxonomic position is desired. PASC is a good combination of the two methods.

The Principle of PASC

In the PASC system, pairwise global alignment is performed on complete genomes or particular protein sequences for each viral family, and their percentage of identity is calculated. The number of virus pairs at each percentage is plotted. The distribution of the identities is not evenly spread, but rather clustered into groups of peaks for viruses at strain, species, genus, and subfamily levels. The percentage range of each peak serves as a good reference for

taxonomic classification based on sequence similarities. This method has been applied to polioviruses using the protein and nucleotide sequences of the VP1 gene, as well as the whole genome sequence, coronaviruses using the protein sequences of the polymerase and helicase, potyviruses using the protein and nucleotide sequences of the complete ORF and the coat protein gene, geminiviruses using the complete sequences of DNA-A, flexiviruses using the protein and nucleotide sequences of the three major viral gene products (replication protein, triple gene block and coat protein), papillomaviruses using the nucleotide sequences of the L1 gene, and poxviruses using the protein sequences of the DNA polymerase. There is an increasing interest to expand PASC to other virus families.

In order to apply PASC to a larger number of virus families and be used by a wide range of virologists, the following should be considered:

1. The same algorithm and sequence dataset should be used to determine the demarcations and to place new viruses in the right taxonomic position.
2. The sequence dataset used for demarcation determination and the virus taxonomy database should be updated frequently to reflect the most recent status.
3. The algorithm should be robust and fast enough for large sequence sets.
4. The system should be readily accessible to researchers worldwide and easy to use.

PASC Implementation at NCBI

The National Center for Biotechnology Information (NCBI) has developed a web-based PASC system that meets all of the criteria mentioned above. In this implementation, complete viral genomes are organized into groups corresponding to broad taxonomic entities such as family or floating genus. Within each group, alignments are pre-computed and stored in a database for each pair of the genomes. The alignments are used to evaluate identities, defined as the ratio of matching residues over the total alignment length. The alignments are computed using the pairwise global algorithm with the affine scoring scheme assigning one to matches and minus one to mismatches and nonterminal spaces and gaps. Since the genomes vary in lengths, terminal spaces are not penalized during the alignment computing but taken into account when computing the identity.

PASC interface is built around a histogram of pairwise identities. The primary feature of the interface is the comparison of an external sequence such as a newly sequenced viral genome, with genomes in a user-selected group. After the sequence is submitted, PASC will start computing the alignments, or extracting them from the database if the query is a member of the group. At the end of the process, a user is presented with a list of closest matches. Matches can be selected to visualize their positions on the identity distribution chart.

The PASC system at NCBI not only reproduced results for virus families for which PASC had been applied to, but also generated data with well-separated identity distributions that can be used as taxonomy demarcations for other virus families such as *Caliciviridae*, *Flaviviridae*, and *Togaviridae* among others.

Applications of PASC

PASC can be used to define taxonomy demarcations for many viral families. Two examples are shown here. In the first example, 45 complete genomes from the family *Luteoviridae* were used to construct the distribution of the pairwise identities among the genomes (**Figure 1**). Pairs located at 88% and up are all from different strains in the same species; pairs between 53% and 85% are mostly from different species in the same genus; and pairs located at 52% and lower are all from different genera. These percentages can therefore serve as demarcations for classification of luteoviruses. In the second example, the pairwise identities of 38 RNA-dependent RNA polymerase (RdRp) gene segment of viruses in the family *Reoviridae* were calculated and plotted (**Figure 2**). Similar to the above mentioned example, 81% and up, between 59% and 76%, and 57% and below can be used as boundaries for strains, species, and genera of reoviruses based on the identities between their polymerase genes. It should be noted that the determination of demarcation using PASC is not always straightforward. For some virus families, phenotypic characteristics of the viruses are required to be taken into account.

PASC can place newly sequenced viruses into the correct taxonomy group. For example, a genomic sequence of a luteovirus (GenBank accession number AY956384) appeared recently in the international sequence databases with the name chickpea chlorotic stunt virus, which is not an official ICTV species name. When this sequence was tested with the luteoviruses in the PASC system, it was found that the virus with the highest sequence similarity to it is cucurbit aphid-borne yellows virus in the genus *Polerovirus*. The similarity is 61.7%, which is in the demarcation of different species in the same genus. It can thus be suggested that this virus is a member of a new species in the genus *Polerovirus*.

Finally, PASC can identify possible questionable classifications in the existing groups when the peaks on the graph are very well separated. **Table 1** lists the pairs of the RdRp segment of reoviruses whose identities are between 54% and 54.5% in **Figure 2**. From the description above, this region represents pairs of viruses from different genera.

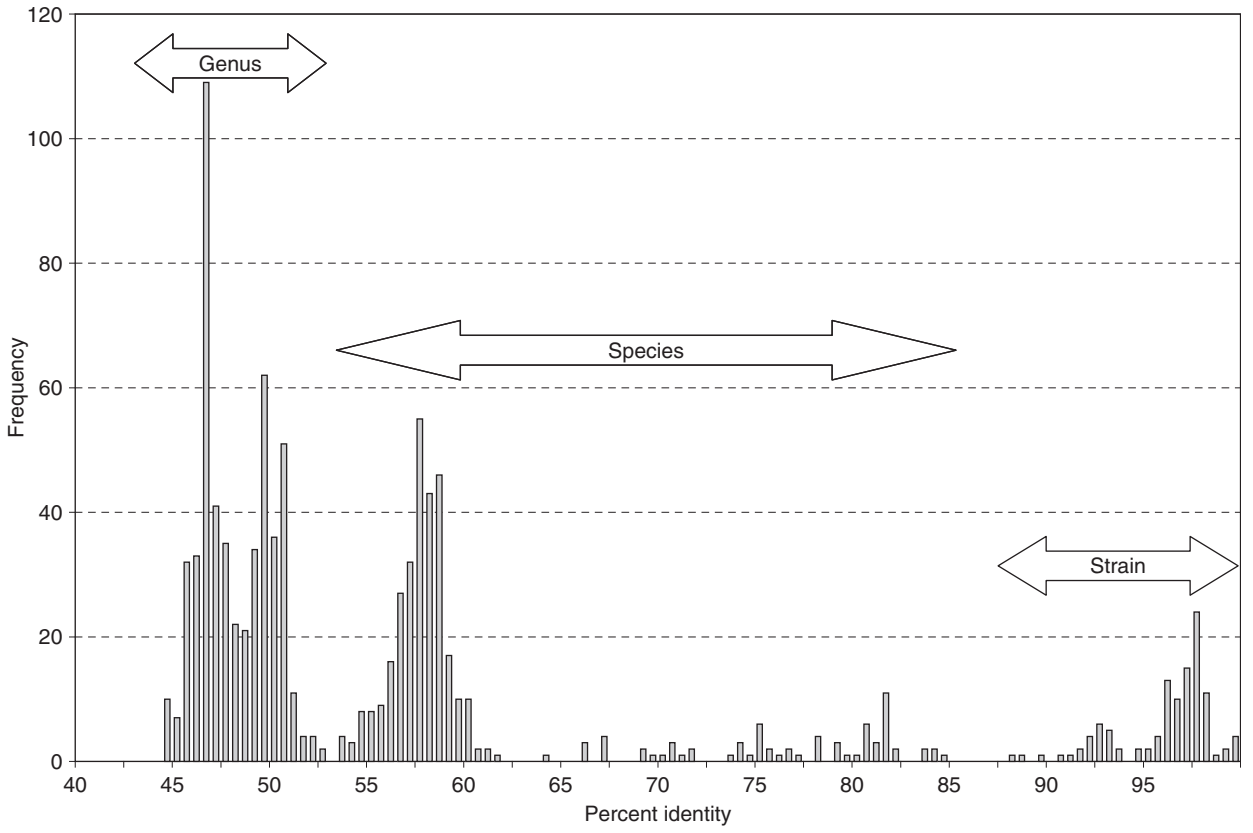

Figure 1 Frequency distribution of pairwise identities from the complete nucleotide sequence comparison of 45 luteoviruses.

This is true for most of the pairs in the table. However, the group also includes a pair containing St. Croix river virus and palyam virus, which both currently belong to the genus *Orbivirus*. Further investigation using PASC revealed that palyam virus has identities higher than 59% with many other viruses in the family, and therefore is indeed an orbivirus. The highest identity of St. Croix river virus with other viruses is only about 54%, which is lower than the demarcation for species in the same genus. This suggests that the species *St. Croix river virus* should probably be placed in a new genus in the *Reoviridae* family.

Advantages of PASC Compared to Other Methods

Unlike other classification methods based on the phenotypic properties of viruses, PASC is a quantitative tool. For those virus families that are suitable for PASC analyses, demarcations can be easily determined and new viruses can be clearly placed into the correct taxonomy. However, there are times when PASC alone cannot give a definite classification, and other viral properties have to be considered.

Compared with another quantitative approach, phylogenetic analysis, PASC is less computationally intensive and can be easily updated with new sequence data. In addition, PASC results are relatively easier to interpret, which can be potentially done by a computer program without human intervention. It would therefore be possible to set up an automatic system for high throughput classification.

Many researchers use BLAST to search sequence databases to find best matches for viral sequences of interest. Although BLAST is readily available and easy to run, it is not the best tool for virus classification. This is because BLAST is a local alignment program, and, as discussed above, it may not take highly variable regions into account when calculating identities. Even when an output from BLAST covers the whole sequence as a single alignment, information about the taxonomy relationship between the query virus and the virus closest to it is not immediately available. For example, an identity of 75% could be within the range of the same species in one viral family, but in the range of different species in another family. On the contrary, PASC suggests explicitly whether the query virus is in the same species as some existing viruses, or if it should be assigned within a new species or genus in the family.

The total number of virus sequences in the GenBank/EMBL/DDBJ databases is more than 4 times now than 5 years ago (from about 109 000 to about 446 000 in

October 2006). It is possible to test the PASC system on many virus families now. New sequencing technology makes it possible to generate large amounts of virus sequences from environmental samples without the need to isolate and purify virus particles. In such cases, a molecular based method is the only way to classify the viral sequences, and PASC can be very useful for this purpose.

Limitations of PASC

Although PASC has been applied successfully to several virus families, the approach has some limitations.

First of all, PASC is not suitable for virus families whose current classification is largely based on virus morphologies, such as phages in the families *Siphoviridae* and *Podoviridae*. The whole genome PASC may not work well for virus families with highly diverse sequences. This includes viruses with low overall sequence similarities or large differences in genome sizes and organization. For example, in the family *Herpesviridae*, the percentage of identity between different species in the genus *Varicellovirus* ranges from 39% (between cercopithecine herpesvirus 9 and suid herpesvirus 1) to 83% (between bovine herpesvirus 1 and bovine herpesvirus 5), while the percentage of identity between a virus in the genus *Simplexvirus* and one in the genus *Varicellovirus* could be as high as 54% (between cercopithecine herpesvirus 2 and bovine herpesvirus 5). The overlap of such identities makes it impossible to determine the species and genus demarcations for herpesviruses. In the family *Poxviridae*, the largest genome (canarypox virus) is almost 3 times as big as the smallest one (bovine papular stomatitis virus). The huge differences in the genomes sizes will introduce large artifacts when calculating the identities. In such cases, single gene or a cluster of genes needs to be used in PASC instead of whole genomes. The polymerase protein sequences of poxviruses have been used to perform PASC and a good result was obtained. However, not every single gene can be used for PASC. The genes must be present in all viruses of a family and be very conserved. They need to be tested extensively and accepted by the research community as a useful taxonomic criterion before being applied to the PASC system.

Second, for those families whose PASC were constructed with whole genomes, the query sequences to be tested on PASC to determine their taxonomic positions have to be complete genome sequences as well in order to get an accurate prediction. Although a percentage of identity can be obtained when a partial genome is used, the value will be smaller than what it really should be if a complete genome were used because of the way percentage of identity is calculated in this system. In addition, this value obtained with a partial sequence may not reflect the real taxonomic position of this virus, if, for example, recombination is frequent and important for this virus. This will reduce the number of sequences that can be tested by PASC.

Last, it is almost impossible to get identical PASC results when different methods are used. As mentioned above, there are many pairwise sequence alignment programs available. Even within a single program, variation of parameters can affect alignments. After an alignment is obtained, there can be various ways to calculate the distance. For demarcations computed using different types of distances, it may be difficult to choose a rational reason to privilege one demarcation threshold over another. Moreover, once a demarcation is adopted and a researcher uses a different definition to measure the distance between a new virus and an existing one, the comparison with the histogram will sometimes be misleading. These issues can be overcome by using a centralized PASC system where the alignment identities of new viruses are computed using the same algorithm and the same parameter set that were used to compute identities within the family and to create the demarcation.

Conclusion

PASC is a molecular classification tool for many virus families. It calculates the pairwise identities of virus sequences within a virus family and displays their distributions, and can help determine the demarcations at strains, species, genera, and subfamilies level. PASC has many advantages over conventional virus classification methods. The tool has been successfully applied to many virus families, although it may not work well for virus families with highly diverse sequences. The PASC tool at NCBI established distributions of identity for a number of virus families. A new virus sequence can be tested with this system within a few minutes to suggest the taxonomic position of the virus in these families. This system eliminates the potential discrepancies in the results caused by different algorithms and/or different data used by the virology community. Data in the system can be updated automatically to reflect changes in virus taxonomy and additions of new virus sequences to the public database. The web interface of the tool makes it easy to navigate and perform analyses.

Glossary

Annotation The process of adding descriptive information to a data set and the individual data elements that comprise that data set. May include both computational analyses and manual curation.
Curation The process of manually adding descriptive information or explanatory material to a data set usually based on a review of the existing literature.
Database A collection of information, usually stored electronically on a computer.
Database, hierarchical (XML) Extensible markup language. A formally defined hierarchical organization of data.
Database management system (DBMS) A database software package designed to operate on a particular computer platform and operating system.
Database schema A map of the database structure, including all of the fields, tables, and relationships that comprise the framework for storage of information within that database.
Database, relational A database structure that provides the ability to define formal relationships between all data elements stored within the database.
Ontology A controlled vocabulary used to formally describe (for our purposes) a biological process or entity.
SQL Structured Query Language. A computer language used to query relational databases for information.

Introduction

In 1955, Niu and Frankel-Conrat published the C-terminal amino acid sequence of tobacco mosaic virus capsid protein. The complete 158-amino-acid sequence of this protein was published in 1960. The first completely sequenced viral genome published was that of bacteriophage MS2 in 1976 (GenBank accession number V00642). Sanger used DNA from bacteriophage phiX174 (J02482) in developing the dideoxy sequencing method, while the first animal viral genome, SV40 (J02400), was sequenced using the Maxam and Gilbert method and published in 1978. Viruses therefore played a pivotal role in the development of modern-day sequencing methods, and viral sequence information (both protein and nucleotide) formed a substantial subset of the earliest available biological databases. In 1965, Margaret O. Dayhoff published the first publicly available database of biological sequence information. This *Atlas of Protein Sequence and Structure* was available only in printed form and contained the sequences of approximately 50 proteins. Establishment of a database of nucleic acid sequences began in 1979 through the efforts of Walter Goad at the US Department of Energy's Los Alamos National Laboratory (LANL) and separately at the European Molecular Biology Laboratories (EMBL) in the early 1980s. In 1982, the LANL database received funding from the National Institutes of Health (NIH) and was christened GenBank. In December of 1981, the Los Alamos Sequence Library contained 263 sequences of which 50 were from eukaryotic viruses and 12 were from bacteriophages. By its tenth release in 1983, GenBank contained 1865 sequences (1 827 214 nucleotides) of which 449 (457 721 nucleotides) were viral. In August of 2006, GenBank (release 154) contained approximately 59 000 000 records, including 367 000 viral sequences.

The number of available sequences has increased exponentially as sequencing technology has improved. In addition, other high-throughput technologies have been developed in recent years, such as those for gene expression and proteomic studies. All of these technologies generate enormous new data sets at ever-increasing rates. The challenge, therefore, has been to provide computational systems that support the storage, retrieval, analysis, and display of this information so that the research scientist can take advantage of this wealth of

resources to ask and answer questions relevant to his or her work. Every article in this encyclopedia contains knowledge that has been derived in part from the analysis of large data sets. The ability to effectively and efficiently utilize these data sets is directly dependent on the databases that have been developed to support storage of this information. Fortunately, the continual development and improvement of data-intensive biological technologies has been matched by the development and improvement of computational technologies. This work, which includes both the development and utilization of databases as well as tools for storage and analysis of biological information, forms a very important part of the bioinformatics field. This article provides an overview of database structure and how that structure supports the storage of biological information. The different types of data associated with the analysis of viruses are discussed, followed by a review of some of the various online databases that store general biological information as well as virus-specific information.

Databases

Definition

A database is simply a collection of information, including the means to store, manipulate, retrieve, and share that information. For many of us, lab notebook fulfilled our initial need for a 'database'. However, this information storage vehicle did not prove to be an ideal place to archive our data. Backups were difficult, and retrieval more so. The advent of computers – especially the desktop computer – provided a new solution to the problem of data storage. Though initially this innovation took the form of spreadsheets and electronic notebooks, the subsequent development of both personal and large-scale database systems provided a much more robust solution to the problems of data storage, retrieval, and manipulation. The computer program supplying this functionality is called a 'database management system' (DBMS). Such systems provide at least four things: (1) the necessary computer code to guide a user through the process of database design; (2) a computer language that can be used to insert, manipulate, and query the data; (3) tools that allow the data to be exported in a variety of formats for sharing and distribution; and (4) the administrative functions necessary to ensure data integrity, security, and backup. However, regardless of the sophistication and diverse functions available in a typical modern DBMS, it is still up to the user to provide the proper context for data storage. The database must be properly designed to ensure that it supports the structure of the data being stored and also supports the types of queries and manipulations necessary to fully understand and efficiently analyze the properties of the data.

Data

The development of a database begins with a description of the data to be stored, all of the parameters associated with the data, and frequently a diagram of the format that will be used. The format used to store the data is called the database schema. The schema provides a detailed picture of the internal format of the database that includes specific containers to store each individual piece of data. While databases can store data in any number of different formats, the design of the particular schema used for a project is dependent on the data and the needs and expertise of the individuals creating, maintaining, and using the database. As an example, we will explore some of the possible formats for storing viral sequence data and provide examples of the database schema that could be used for such a project.

Figure 1(**a**) provides an example of a GenBank sequence record that is familiar to most biologists. These records are provided in a 'flat file' format in which all of the information associated with this particular sequence is provided in a human-readable form and in which all of the information is connected in some manner to the original sequence. In this format, the relationships between each piece of information and every other piece of information are only implicitly defined, that is, each line starts with a label that describes the information in the rest of the line, but it is up to the investigator reading the record to make all of the proper connections between each of the data fields (lines). The proper connections are not explicitly defined in this record. As trained scientists, we are able to read the record in **Figure 1**(**a**) and discern that this particular amino acid sequence is derived from a strain of Ebola virus that was studied by a group in Germany, and that this sequence codes for a protein that functions as the virus RNA polymerase. The format of this record was carefully designed to allow us, or a computer, to pull out each individual type of information. However as trained scientists, we already understand the proper connections between the different information fields in this file. The computer does not. Therefore, to analyze the data using a computer, a custom software program must be written to provide access to the data.

Extensible markup language (XML) is another widely used format for storing database information. **Figure 1**(**b**) shows an example of part of the XML record for the Ebola virus polymerase protein. In this format, each data field can be many lines long; the start and end of a data record contained within a particular field are indicated by tags made of a label between two brackets ('<label>...</label>'). Unlike the lines in the GenBank record in **Figure 1**(**a**), a field in an XML record can be placed inside of another, defining a structure and a relationship between them. For example, the *TSeq_orgname* is placed inside of the *TSeq* record to show that this

Figure 1 Data formats. Examples of two different formats for organizing sequence data are shown. (a) An example of a GenBank flat file sequence record. (b) Part of the same record using a hierarchical XML format.

organism name applies only to that sequence record. If the file contained multiple sequences, each *TSeq* field would have its own *TSeq_orgname* subfield, and the relationship between them would be very clear. This self-describing hierarchical structure makes XML very powerful for expressing many types of data that are hard to express in a single table, such as that used in a spreadsheet. However, in order to find any piece of information in the XML file,

a user (with an appropriate search program) needs to traverse the whole file in order to pull out the particular items of data that are of interest. Therefore, while an XML file may be an excellent format for defining and exchanging data, it is often not the best vehicle for efficiently storing and querying that data. That is still the realm of the relational database.

'Relational database management systems' (RDBMSs) are designed to do two things extremely well: (1) store and update structured data with high integrity, and (2) provide powerful tools to search, summarize, and analyze the data. The format used for storing the data is to divide it into several tables, each of which is equivalent to a single spreadsheet. The relationships between the data in the tables are then defined, and the RDBMS ensures that all data follow the rules laid out by this design. This set of tables and relationships is called the schema. An example diagram of a relational database schema is provided in **Figure 2**. This Viral Genome Database (VGD) schema is an idealized version of a database used to store viral genome sequences, their associated gene sequences, and associated descriptive and analytical information. Each box in **Figure 2** represents a single object or concept, such as a genome, gene, or virus, about which we want to store data and is contained in a single table in the RDBMS. The names listed in the box are the columns of that table, which hold the various types of data about the object. The 'gene' table therefore contains columns holding data such as the name of the gene, its coding strand, and a description of its function. The RDBMS is

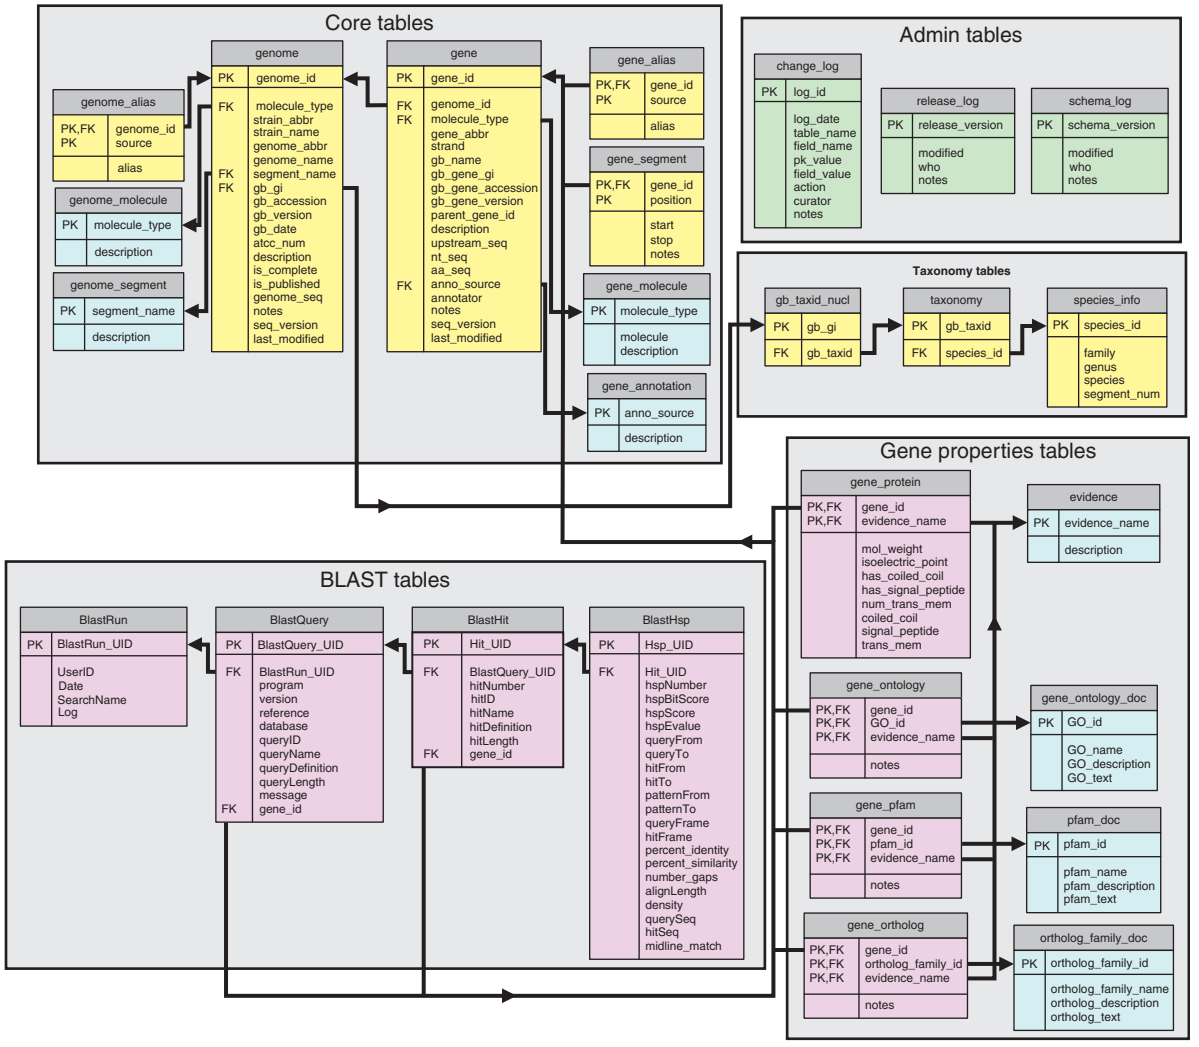

Figure 2 VGD Database schema. Underlying structure of a Viral Genome Sequence Database (VGD). Data tables are grouped according to the type of information contained in each set of tables. Each table contains a set of fields that hold a particular type of data. Lines and arrows display the relationships between fields as defined by the foreign key (FK) and primary key (PK) that connect two tables. (Each arrow points to the table containing the primary key.) Tables are color-coded according to the source of the information they contain: yellow, data obtained from the original GenBank sequence record and the ICTV Eighth Report; pink, data obtained from automated annotation or manual curation; blue, controlled vocabularies to ensure data consistency; green, administrative data.

able to enforce a series of rules for tables that are linked by defining relationships that ensure data integrity and accuracy. These relationships are defined by a foreign key in one table that links to corresponding data in another table defined by a primary key. In this example, the RDMS can check that every gene in the 'gene' table refers to an existing genome in the 'genome' table, by ensuring that each of these tables contains a matching 'genome_id'. Since any one genome can code for many genes, many genes may contain the same 'genome_id'. This defines what is called a one-to-many relationship between the 'genome' and 'gene' tables. All of these relationships are identified in **Figure 2** by arrows connecting the tables.

Because viruses have evolved a variety of alternative coding strategies such as splicing and RNA editing; it is necessary to design the database so that these processes can be formally described. The 'gene_segment' table specifies the genomic location of the nucleotides that code for each gene. If a gene is coded in the traditional manner – one ORF, one protein – then that gene would have one record in the 'gene_segment' table. However, as described above, if a gene is translated from a spliced transcript, it would be represented in the 'gene_segment' table by two or more records, each of which specifies the location of a single exon. If an RNA transcript is edited by stuttering of the polymerase at a particular run of nucleotides, resulting in the addition of one or more nontemplated nucleotides, then that gene will also have at least two records in the 'gene_segment' table. In this case, the second 'gene_segment' record may overlap the last base of the first record for that gene. In this manner, an extra, nontemplated base becomes part of the final gene transcript. Other more complex coding schemes can also be identified using this, or similar, database structures.

The tables in **Figure 2** are grouped according to the type of information they contain. Though the database itself does not formally group tables in this manner, database schema diagrams are created to benefit database designers and users by enhancing their ability to understand the structure of the database. These diagrams make it easier to both populate the database with data and query the database for information. The core tables hold basic biological information about each viral strain and its genomic sequence (or sequences if the virus contains segmented genomes) as well as the genes coded for by each genome. The taxonomy tables provide the taxonomic classification of each virus. Taxonomic designations are taken directly from the *Eighth Report of the International Committee on Taxonomy of Viruses* (ICTV). The 'gene properties' tables provide information related to the properties of each gene in the database. Gene properties may be generated from computational analyses such as calculations of molecular weight and isoelectric point (pI) that are derived from the amino acid sequence. Gene properties may also be derived from a manual curation process in which an investigator might identify, for example, functional attributes of a sequence based on evidence provided from a literature search. Assignment of 'gene ontology' terms (see below) is another example of information provided during manual curation. The BLAST tables store the results of similarity searches of every gene and genome in the VGD searched against a variety of sequence databases using the National Center for Biotechnology Information (NCBI) BLAST program. Examples of search databases might include the complete GenBank nonredundant protein database and/or a database comprised of all the protein sequences in the VGD itself. While most of us store our BLAST search results as files on our desktop computers, it is useful to store this information within the database to provide rapid access to similarity results for comparative purposes; to use these results to assign genes to orthologous families of related sequences; and to use these results in applications that analyze data in the database and, for example, display the results of an analysis between two or more types of viruses showing shared sets of common genes. Finally, the 'admin' tables provide information on each new data release, an archive of old data records that have been subsequently updated, and a log detailing updates to the database schema itself.

It is useful for database designers, managers, and data submitters to understand the types of information that each table contains and the source of that information. Therefore, the database schema provided in **Figure 2** is color-coded according to the type and source of information each table provides. Yellow tables contain basic biological data obtained either directly from the GenBank record or from other sources such as the ICTV. Pink tables contain data obtained as the result of either computational analyses (BLAST searches, calculations of molecular weight, functional motif similarities, etc.) or from manual curation. Blue tables provide a controlled vocabulary that is used to populate fields in other tables. This ensures that a descriptive term used to describe some property of a virus has been approved for use by a human curator, is spelled correctly, and when multiple terms or aliases exist for the same descriptor, the same one is always chosen.

While the use of a controlled vocabulary may appear trivial, in fact, misuse of terms, or even misspellings, can result in severe problems in computer-based databases. The computer does not know that the terms 'negative-sense RNA virus' and 'negative-strand RNA virus' may both be referring to the same type of virus. The provision and use of a controlled vocabulary increases the likelihood that these terms will be used properly, and ensures that the fields containing these terms will be easily comparable. For example, the 'genome_molecule' table contains the following permissible values for 'molecule_type': 'ambisense ssRNA', 'dsRNA', 'negative-sense ssRNA', 'positive-sense ssRNA', 'ssDNA', and 'dsDNA'. A particular viral genome must then have one of these values entered into the 'molecule_type' field

of the 'genome' table, since this field is a foreign key to the 'molecule_type' primary key of the 'genome_molecule' table. Entering 'double-stranded DNA' would not be permissible.

Annotation

Raw data obtained directly from high-throughput analytical techniques such as automated sequencing, protein interaction, or microarray experiments contain little-to-no information as to the content or meaning. The process of adding value to the raw data to increase the knowledge content is known as annotation and curation. As an example, the results of a microarray experiment may provide an indication that individual genes are up- or downregulated under certain experimental conditions. By annotating the properties of those genes, we are able to see that certain sets of genes showing coordinated regulation are a part of common biological pathways. An important pattern then emerges that was not discernable solely by inspection of the original data. The annotation process consists of a semiautomated analysis of the information content of the data and provides a variety of descriptive features that aid the process of assigning meaning to the data. The investigator is then able to use this analytical information to more closely inspect the data during a manual curation process that might support the reconstruction of gene expression or protein interaction pathways, or allow for the inference of functional attributes of each identified gene. All of this curated information can then be stored back in the database and associated with each particular gene.

For each piece of information associated with a gene (or other biological entity) during the process of annotation and curation, it is always important to provide the evidence used to support each assignment. This evidence may be described in a Standard Operating Procedure (SOP) document which, much like an experimental protocol, details the annotation process and includes a description of the computer algorithms, programs, and analysis pipelines that were used to compile that information. Each piece of information annotated by the use of this pipeline might then be coded, for example, 'IEA: Inferred from Electronic Annotation'. For information obtained from the literature during manual curation, the literature reference from which the information was obtained should always be provided along with a code that describes the source of the information. Some of the possible evidence codes include 'IDA: Inferred from Direct Assay', 'IGI: Inferred from Genetic Interaction', 'IMP: Inferred from Mutant Phenotype', or 'ISS: Inferred from Sequence or Structural Similarity'. These evidence codes are taken from a list provided by the Gene Ontology (GO) Consortium (see below) and as such represent a controlled vocabulary that any data curator can use and that will be understood by anyone familiar with the GO database. This controlled evidence vocabulary is stored in the 'evidence' table, and each record in every one of the gene properties tables is assigned an evidence code noting the source of the annotation/curation data.

As indicated above, the use of controlled vocabularies (ontologies) to describe the attributes of biological data is extremely important. It is only through the use of these controlled vocabularies that a consistent, documented approach can be taken during the annotation/curation process. And while there may be instances where creating your own ontology may be necessary, the use of already available, community-developed ontologies ensures that the ontological descriptions assigned to your database will be understood by anyone familiar with the public ontology. Use of these public ontologies also ensures that they support comparative analyses with other available databases that also make use of the same ontological descriptions. The GO Consortium provides one of the most extensive and widely used controlled vocabularies available for biological systems. GO describes biological systems in terms of their biological processes, cellular components, and molecular functions. The GO effort is community-driven, and any scientist can participate in the development and refinement of the GO vocabulary. Currently, GO contains a number of terms specific to viral processes, but these tend to be oriented toward particular viral families, and may not necessarily be the same terms used by investigators in other areas of virology. Therefore it is important that work continues in the virus community to expand the availability and use of GO terms relevant to all viruses. GO is not intended to cover all things biological. Therefore, other ontologies exist and are actively being developed to support the description of many other biological processes and entities. For example, GO does not describe disease-related processes or mutants; it does not cover protein structure or protein interactions; and it does not cover evolutionary processes. A complementary effort is under way to better organize existing ontologies, and to provide tools and mechanisms to develop and catalog new ontologies. This work is being undertaken by the National Center for Biomedical Ontologies, located at Stanford University, with participants worldwide.

Access (Searching for Information)

The most comprehensive, well-designed database is useless if no method has been provided to access that database, or if access is difficult due to a poorly designed application. Therefore, providing a search interface that meets the needs of intended users is critical to fully realizing the potential of any effort at developing a comprehensive database. Access can be provided using a number of different methods ranging from direct query of the database using the relatively standardized 'structured query language' (SQL), to customized applications designed to provide the ability to ask sophisticated questions regarding the data

contained in the database and mine the data for meaningful patterns. Web pages may be designed to provide simple-to-use forms to access and query data stored in an RDBMS.

Using the VGD schema as a data source, one example of an SQL query might be to find the gene_id and name of all the proteins in the database that have a molecular weight between 20 000 and 30 000, and also have at least one transmembrane region.

Many database providers also provide users with the ability to download copies of the database so that these users may analyze the data using their own set of analytical tools.

Output (Utilizing Information)

When a user queries a database using any of the available access methods, the results of that query are generally provided in the form of a table where columns represent fields in the database and the rows represent the data from individual database records. Tabular output can be easily imported into spreadsheet applications, sorted, manipulated, and reformatted for use in other applications. But while extremely flexible, tabular output is not always the best format to use to fully understand the underlying data and the biological implications. Therefore, many applications that connect to databases provide a variety of visualization tools that display the data graphically, showing patterns in the data that may be difficult to discern using text-based output. An example of one such visual display is provided in **Figure 3** and shows conservation of synteny between the genes of two different poxvirus species. The information used to generate this figure comes directly from the data provided in the VGD. Every gene in the two viruses (in this case crocodilepox virus and molluscum contagiosum virus) has been compared to every other gene using the BLAST search program. The results of this search are stored in the BLAST tables of the VGD. In addition, the location of each gene within its respective genomic sequence is stored in the 'gene_segment' table. This information, once extracted from the database server, is initially text but it is then submitted to a program running on the server that reformats the data and creates a graph. In this manner, it is much easier to visualize the series of points formed along a diagonal when there are a series of similar genes with similar genomic locations present in each of the two viruses. These data sets may contain gene synteny patterns that display deletion, insertion, or recombination events during the course of viral evolution. These patterns can be difficult to detect with text-based tables, but are easy to discern using visual displays of the data.

Information provided to a user as the result of a database query may contain data derived from a combination of sources, and displayed using both visual and textual

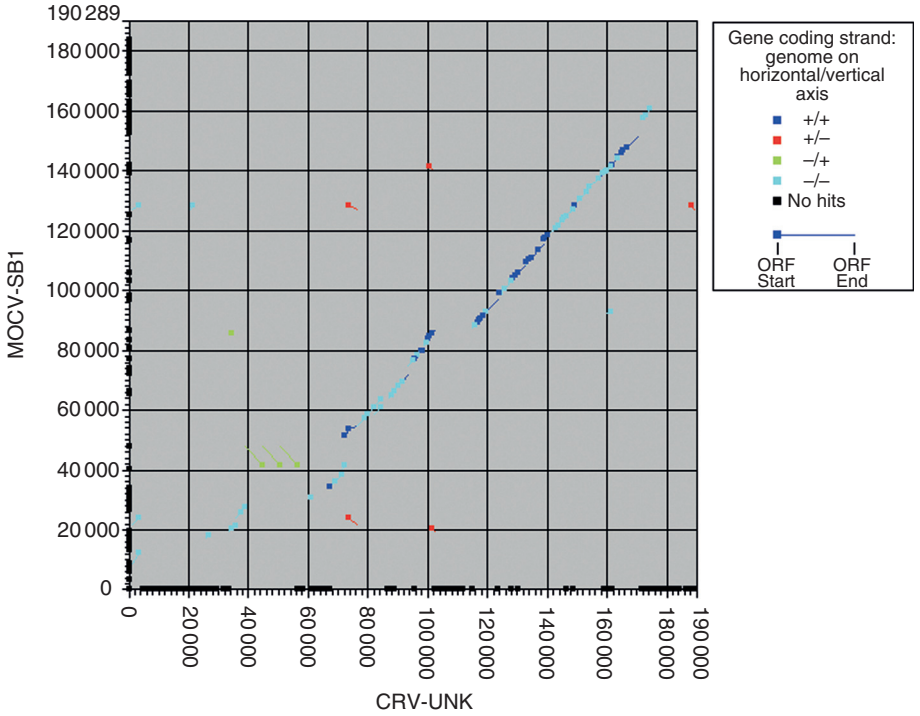

Figure 3 Gene synteny plot. A comparison of gene sequence and genomic position conservation between crocodilepox virus (horizontal axis) and molluscum contagiosum virus (vertical axis). All predicted proteins encoded by each virus were compared to each other using BLASTP. Each pair of proteins showing some measure of similarity, as determined by a BLAST expect (*E*) value <0.00001, was plotted according to the location of each gene on each respective genome. The color of the points reflects the identity of the coding strand of each gene. Black points along either of the two axes represent proteins unique to that genome.

feedback. **Figure 4** shows the web-based output of a query designed to display information related to a particular virus gene. The top of this web page displays the location of the gene on the genome visually showing surrounding genes on a partial map of the viral genome. Basic gene information such as genome coordinates, gene name, and the nucleotide and amino acid sequence are also provided. This information was originally obtained from the original GenBank record and then stored in the VGD database. Data added as the result of an automated annotation pipeline are also displayed. This includes calculated values for molecular weight and pI; amino acid composition; functional motifs; BLAST similarity searches; and predicted protein structural properties such as transmembrane domains, coiled-coil regions, and signal sequences. Finally, information obtained from a manual curation of the gene through an extensive literature search is also displayed. Curated information includes a mini review of gene function; experimentally determined gene properties such as molecular weight, pI, and protein structure; alternative names and aliases used in the literature; assignment of ontological terms describing gene function; the availability of reagents such as antibodies and clones; and also, as available, information on the functional effects of mutations. All of the information to construct the web page for this gene is directly provided as the result of a single database query. (The tables storing the manually curated gene information are not shown in **Figure 2**.) Obviously, compiling the data and entering it into the database required a substantial amount of effort, both computationally and manually; however, the information is now much more available and useful to the research scientist.

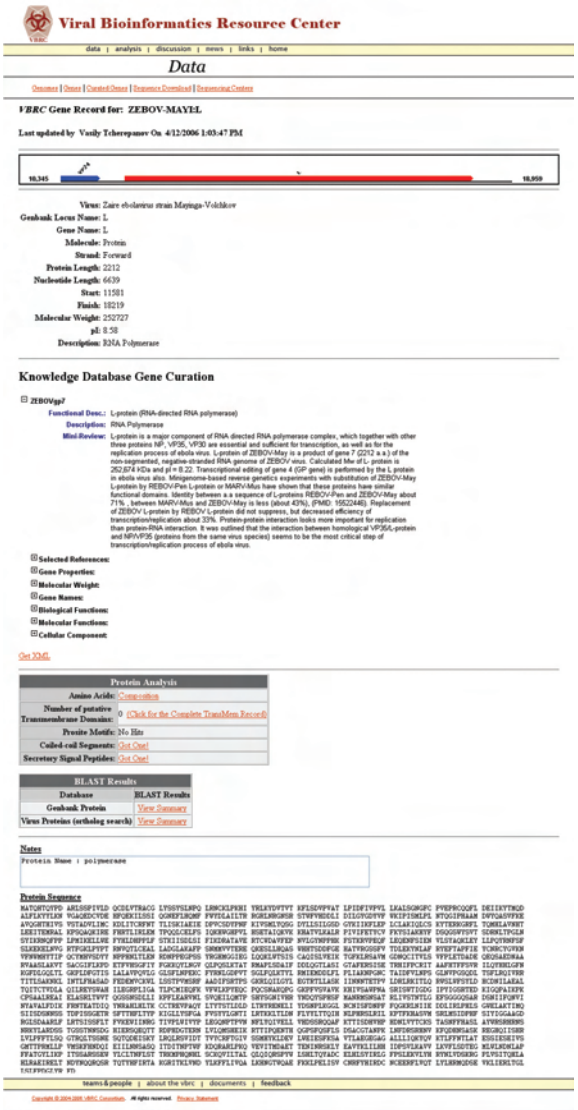

Figure 4 Gene record. An example of a gene record derived from data in the Viral Genome Database. The record contains a map showing the gene's location; basic descriptive information; analytical data; manually curated descriptive information; links to protein sequence analyses and BLAST similarity data; and the gene sequence itself.

Errors

No discussion of databases would be complete without considering errors. As in any other scientific endeavor, the data we generate, the knowledge we derive from the data, and the inferences we make as a result of the analysis of the data are all subject to error. These errors can be introduced at many points in the analytical chain. The original data may be faulty: using sequence data as one example, nucleotides in a DNA sequence may have been misread or miscalled, or someone may even have mistyped the sequence. The database may have been poorly designed; a field in a table designed to hold sequence information may have been set to hold only 2000 characters, whereas the sequences imported into that field may be longer than 2000 nucleotides. The sequences would have then been automatically truncated to 2000 characters, resulting in the loss of data. The curator may have mistyped an Enzyme Commission (EC) number for an RNA polymerase, or may have incorrectly assigned a genomic sequence to the wrong taxonomic classification. Or even more insidious, the curator may have been using annotations provided by other groups that had justified their own annotations on the basis of matches to annotations provided by yet another group. Such chains of evidence may extend far back, and the chance of propagating an early error increases with time. Such error propagation can be widespread indeed, affecting the work of multiple sequencing centers and database creators and providers. This is especially true given the dependencies of genomic sequence annotations on previously published annotations. The possible sources of errors are numerous, and it is the responsibility of both the database provider and the user to be aware of, and on the lookout for, errors. The database provider can, with careful database and

application design, apply error-checking routines to many aspects of the data storage and analysis pipeline. The code can check for truncated sequences, interrupted open reading frames, and nonsense data, as well as data annotations that do not match a provided controlled vocabulary. But the user should always approach any database or the output of any application with a little healthy skepticism. The user is the final arbiter of the accuracy of the information, and it is their responsibility to look out for inconsistent or erroneous results that may indicate either a random or systemic error at some point in the process of data collection and analysis.

Virus Databases

It is not feasible to provide a comprehensive and current list of all available databases that contain virus-related information or information of use to virus researchers. New databases appear on a regular basis; existing databases either disappear or become stagnant and outdated; or databases may change focus and domains of interest. Any resource published in book format attempting to provide an up-to-date list would be out-of-date on the day of publication. Even web-based lists of database resources quickly become out-of-date due to the rapidity with which available resources change, and the difficulty and extensive effort required to keep an online list current and inclusive. Therefore, our approach in this article is to provide an overview of the types of data that are obtainable from available biological databases, and to list some of the more important database resources that have been available for extended periods of time and, importantly, remain current through a process of continual updating and refinement. We should also emphasize that the use of web-based search tools such as Google, various web logs (Blogs), and news groups, can provide some of the best means of locating existing and newly available web-based information sources. Information contained in databases can be used to address a wide variety of problems. A sampling of the areas of research facilitated by virus databases includes

- taxonomy and classification;
- host range, distribution, and ecology;
- evolutionary biology;
- pathogenesis;
- host–pathogen interaction;
- epidemiology;
- disease surveillance;
- detection;
- prevention;
- prophylaxis;
- diagnosis; and
- treatment.

Addressing these problems involves mining the data in an appropriate database in order to detect patterns that allow certain associations, generalizations, cause–effect relationships, or structure–function relationships to be discerned. **Table 1** provides a list of some of the more useful and stable database resources of possible interest to virus researchers. Below, we expand on some of this information and provide a brief discussion concerning the sources and intended uses of these data sets.

Data

Major repositories of biological information

The two major, overarching collections of biological databases are at the NCBI, supported by the National Library of Medicine at the NIH, and the EMBL, part of the European Bioinformatics Institute. These large data repositories try to be all-inclusive, acting as the primary source of publicly available molecular biological data for the scientific community. In fact, most journals require that, prior to publication, investigators submit their original sequence data to one of these repositories. In addition to sequence data, NCBI and EMBL (along with many other data repositories) include a large variety of other data types, such as that obtained from gene-expression experiments and studies investigating biological structures. Journals are also extending the requirement for data deposition to some of these other data types. Note that while much of the data available from these repositories is raw data obtained directly as the result of experimental investigation in the laboratory, a variety of 'value-added' secondary databases are also available that take primary data records and manipulate or annotate them in some fashion in order to derive additional useful information.

When an investigator is unsure about the existence or source of some biological data, the NCBI and EMBL websites should serve as the starting point for locating such information. The NCBI Entrez Search Engine provides a powerful interface to access all information contained in the various NCBI databases, including all available sequence records. A search engine such as Google might also be used if NCBI and EMBL fail to locate the desired information. Of course PubMed, the repository of literature citations maintained at NCBI, also represents a major reference site for locating biological information. Finally, the journal *Nucleic Acids Research* (NAR) publishes an annual 'database' issue and an annual 'web server' issue that are excellent references for finding new biological databases and websites. And while the most recent NAR database or web server issue may contain articles on a variety of new and interesting databases and websites, be sure to also look at issues from previous years. Older issues contain articles on many existing sites that may not necessarily be represented in the latest

journal publication, but are nevertheless still available and current.

There are several websites that serve to provide general virus-specific information and links of use to virus researchers. One of these is the NCBI Viral Genomes Project, which provides an overview of all virus-related NCBI resources including taxonomy, sequence, and reference information. Links to other sources of viral data are provided, as well as a number of analytical tools that have been developed to support viral taxonomic classification and sequence clustering. Another useful site is the All the Virology on the WWW website. This site provides numerous links to other virus-specific websites, databases, information, news, and analytical resources. It is updated on a regular basis and is therefore as current as any site of this scope can be.

Taxonomy and classification

One of the strengths of storing information within a database is that information derived from different sources or different data sets can be compared so that important common and distinguishing features can be recognized. Such comparative analyses are greatly aided by having a rigorous classification scheme for the information being studied. The International Union of Microbiological Societies has designated the International Committee on Taxonomy of Viruses (ICTV) as the official body that determines taxonomic classifications for viruses. Through a series of subcommittees and associated study groups, scientists with expertise on each viral species participate in the establishment of new taxonomic groups, assignment of new isolates to existing or newly established taxonomic groups, and reassessment of existing assignments as additional research data become available. The ICTV uses more than 2600 individual characteristics for classification, though sequence homology has gained increasing importance over the years as one of the major classifiers of taxonomic position. Currently, as described in its Eighth Report, the ICTV recognizes 3 orders, 73 families, 287 genera, and 1950 species of viruses. The ICTV officially classifies viral isolates only to the species level. Divisions within species, such as clades, subgroups, strains, isolates, types, etc., are left to others. The ICTV classifications are available in book form as well as from an online database. This database, the ICTVdb, contains the complete taxonomic hierarchy, and assigns each known viral isolate to its appropriate place in that hierarchy. Descriptive information on each viral species is also available. The NCBI also provides a web-based taxonomy browser for access to taxonomically specified sets of sequence records. NCBI's viral taxonomy is not completely congruent with that of ICTV, but efforts have been under way to ensure congruency with the official ICTV classification.

Nucleotide sequence data

The primary repositories of existing sequence information come from the three organizations that comprise the International Nucleotide Sequence Database Collaboration. These three sites are GenBank (maintained at NCBI), EMBL, and the DNA Data Bank of Japan (DDBJ). Because all sequence information submitted to any one of these entities is shared with the others, a researcher need query only one of these sites to get the most up-to-date set of available sequences. GenBank stores all publicly available nucleotide sequences for all organisms, as well as viruses. This includes whole-genome sequences as well as partial-genome and individual coding sequences. Sequences are also available from large-scale sequencing projects, such as those from shotgun sequencing of environmental samples (including viruses), and high-throughput low- and high-coverage genomic sequencing projects. NCBI provides separate database divisions for access to these sequence datasets. The sequence provided in each GenBank record is the distillation of the raw data generated by (in most cases these days) automated sequencing machines. The trace files and base calls provided by the sequencers are then assembled into a collection of contiguous sequences (contigs) until the final sequence has been assembled. In recognition of the fact that there is useful information contained in these trace files and sequence assemblies (especially if one would like to look for possible sequencing errors or polymorphisms), NCBI now provides separate Trace File and Assembly Archives for GenBank sequences when the laboratory responsible for generating the sequence submits these files. Currently, the only viruses represented in these archives are influenza A, chlorella, and a few bacteriophages.

An important caveat in using data obtained from GenBank or other sources is that no sequence data can be considered to be 100% accurate. Furthermore, the annotation associated with the sequence, as provided in the GenBank record, may also contain inaccuracies or be out-of-date. GenBank records are provided and maintained by the group originally submitting the sequence to GenBank. GenBank may review these records for obvious errors and formatting mistakes (such as the lack of an open reading frame where one is indicated), but given the large numbers of sequences being submitted, it is impossible to verify all of the information in these records. In addition, the submitter of a sequence essentially 'owns' that sequence record and is thus responsible for all updates and corrections. NCBI generally will not change any of the information in the GenBank record unless the sequence submitter provides the changes. In some cases, sequence annotations will be updated and expanded, but many, if not most, records never change following their initial submission. (These facts emphasize the responsibility that submitters of sequence data have to ensure the accuracy of their

original submission and to update their sequence data and annotations as necessary.) Therefore, the user of the information has the responsibility to ensure, to the extent possible, its accuracy is sufficient to support any conclusions derived from that information. In recognition of these problems, NCBI established the Reference Sequence (RefSeq) database project, which attempts to provide reference sequences for genomes, genes, mRNAs, proteins, and RNA sequences that can be used, in NCBI's words, as "a stable reference for gene characterization, mutation analysis, expression studies, and polymorphism discovery". RefSeq records are manually curated by NCBI staff, and therefore should provide more current (and hopefully more accurate) sequence annotations to support the needs of the research community. For viruses, RefSeq provides a complete genomic sequence and annotation for one representative isolate of each viral species. NCBI solicits members of the research community to participate as advisors for each viral family represented in RefSeq, in an effort to ensure the accuracy of the RefSeq effort.

Protein sequence data

In addition to the nucleotide sequence databases mentioned above, UniProt provides a general, all-inclusive protein sequence database that adds value through annotation and analysis of all the available protein sequences. UniProt represents a collaborative effort of three groups that previously maintained separate protein databases (PIR, SwissProt, and TrEMBL). These groups, the National Biomedical Research Foundation at Georgetown University, the Swiss Institute of Bioinformatics, and the European Bioinformatics Institute, formed a consortium in 2002 to merge each of their individual databases into one comprehensive database, UniProt. UniProt data can be queried by searching for similarity to a query sequence, or by identifying useful records based on the text annotations. Sequences are also grouped into clusters based on sequence similarity. Similarity of a query sequence to a particular cluster may be useful in assigning functional characteristics to sequences of unknown function. NCBI also provides a protein sequence database (with corresponding RefSeq records) consisting of all protein-coding sequences that have been annotated within all GenBank nucleotide sequence records.

Virus-specific sequence databases

The above-mentioned sequence databases are not limited to viral data, but rather store sequence information for all biological organisms. In many cases, access to nonviral sequences is necessary for comparative purposes, or to study virus–host interactions. But it is frequently easier to use virus-specific databases when they exist, to provide a more focused view of the data that may simplify many of the analyses of interest. **Table 1** lists many of these virus-specific sites. Sites of note include the NIH-supported Bioinformatics Resource Centers for Biodefense and Emerging and Reemerging Infectious Diseases (BRCs). The BRCs concentrate on providing databases, annotations, and analytical resources on NIH priority pathogens, a list that includes many viruses. In addition, the LANL has developed a variety of viral databases and analytical resources including databases focusing on HIV and influenza. For plant virologists, the Descriptions of Plant Viruses (DPV) website contains a comprehensive database of sequence and other information on plant viruses.

Structural information

The three-dimensional structures for quite a few viral proteins and virion particles have been determined. These structures are available in the primary database for experimentally determined structures, the Protein Data Bank (PDB). The PDB currently contains the structures for more than 650 viral proteins and viral protein complexes out of 38 000 total structures. Several virus-specific structure databases also exist. These include the VIPERdb database of icosahedral viral capsid structures, which provides analytical and visualization tools for the study of viral capsid structures; Virus World at the Institute for Molecular Virology at the University of Wisconsin, which contains a variety of structural images of viruses; and the Big Picture Book of Viruses, which provides a catalog of images of viruses, along with descriptive information.

Functional motifs and orthologous clusters

Ultimately, the biology of viruses is determined by genomic sequence (with a little help from the host and the environment). Nucleotide sequences may be structural, functional, regulatory, or protein coding. Protein sequences may be structural, functional, and/or regulatory, as well. Patterns specified in nucleotide or amino acid sequences can be identified and associated with many of these biological roles. Both general and virus-specific databases exist that map these roles to specific sequence motifs. Most also provide tools that allow investigators to search their own sequences for the presence of particular patterns or motifs characteristic of function. General databases include the NCBI Conserved Domain Database; the Pfam (protein family) database of multiple sequence alignments and hidden Markov models; and the PROSITE database of protein families and domains. Each of these databases and associated search algorithms differ in how they detect a particular search motif or define a particular protein family. It can therefore be useful to employ multiple databases and search methods when analyzing a new sequence (though in many cases they will each detect a similar set of putative functional motifs). InterPro is a database of protein families, domains, and functional sites that combines many other existing motif databases. InterPro

provides a search tool, InterProScan, which is able to utilize several different search algorithms dependent on the database to be searched. It allows users to choose which of the available databases and search tools to use when analyzing their own sequences of interest. A comprehensive report is provided that not only summarizes the results of the search, but also provides a comprehensive annotation derived from similarities to known functional domains. All of the above databases define functional attributes based on similarities in amino acid sequence. These amino acid similarities can be used to classify proteins into functional families. Placing proteins into common functional families is also frequently performed by grouping the proteins into orthologous families based on the overall similarity of their amino acid sequence as determined by pairwise BLAST comparisons. Two virus-specific databases of orthologous gene families are the Viral Clusters of Orthologous Groups database (VOGs) at NCBI, and the Viral Orthologous Clusters database (VOCs) at the Viral Bioinformatics Resource Center and Viral Bioinformatics, Canada.

Other information

Many other types of useful information, both general and virus-specific, have been collected into databases that are available to researchers. These include databases of gene-expression experiments (NCBI Gene Expression Omnibus – GEO); protein–protein interaction databases, such as the NCBI HIV Protein-Interaction Database; The Immune Epitope Database and Analysis Resource (IEDB) at the La Jolla Institute for Allergy and Immunology; and databases and resources for defining and visualizing biological pathways, such as metabolic, regulatory, and signaling pathways. These pathway databases include Reactome at the Cold Spring Harbor Laboratory, New York; BioCyc at SRI International, Menlo Park, California; and the Kyoto Encyclopedia of Genes and Genomes (KEGG) at Kyoto University in Japan.

Analytical Tools

As indicated above, the information contained in a database is useless unless there is some way to retrieve that information from the database. In addition, having access to all of the information in every existing database would be meaningless unless tools are available that allow one to process and understand the data contained within those databases. Therefore, a discussion of virus databases would not be complete without at least a passing reference to the tools that are available for analysis. To populate a database such as the VGD with sequence and analytical information, and to utilize this information for subsequent analyses, requires a variety of analytical tools including programs for

- sequence record reformatting,
- database import and export,
- sequence similarity comparison,
- gene prediction and identification,
- detection of functional motifs,
- comparative analysis,
- multiple sequence alignment,
- phylogenetic inference,
- structural prediction, and
- visualization.

Sources for some of these tools have already been mentioned, and many other tools are available from the same websites that provide many of the databases listed in **Table 1**. The goal of all of these sites that make available data and analytical tools is to provide – or enable the discovery of – knowledge, rather than simply providing access to data. Only in this manner can the ultimate goal of biological understanding be fully realized.

Virus Entry to Bacterial Cells

M M Poranen and A Domanska, University of Helsinki, Helsinki, Finland

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Adsorption Initial interaction between a virus particle and a cellular receptor molecule.
Bacteriophage (or phage) A virus that infects bacteria.
Capsid The protective protein coat of a virus particle.
Cell envelope Plasma membrane and cellular structures located outside the plasma membrane.
Cell wall Cellular structures located outside the plasma membrane.
Lipopolysaccharide A unique glycolipid of the outer membrane of Gram-negative bacteria.
Peptidoglycan A polymer consisting of long glycan chains cross-linked via peptide bridges and forming homogenous layer outside the plasma membrane of eubacteria component of the cell wall.
Receptor A specific molecule or molecular assembly exposed on the surface of a cell to which a virus entering the cell attaches.
Receptor-binding protein A virion protein responsible for the interaction of a virion with a specific cellular receptor molecule.
Vertex Fivefold symmetry position of the icosahedra; one icosahedral particle has 12 fivefold symmetry positions.
Viral envelope An outer lipid–protein bilayer of a virus.
Virion A virus particle, the extracellular form of a virus.

Introduction

Viruses are intracellular parasites that are dependent on the metabolic apparatus of the cell. Unlike other parasitic self-replicating systems, like plasmids and viroids, viruses possess an extracellular phase that allows spread from one infected cell or organism to another. Consequently, viruses have to have means to infect new host cells. The entry into a suitable host cell is a key event for the viral reproduction and survival.

Host Cell Barriers

The nature of the host cell wall has a great influence on the viral entry strategy. Gram-positive bacteria have a single internal lipid bilayer and a thick cell wall made of peptidoglycan while Gram-negative cells are covered by an internal membrane, a thin layer of peptidoglycan, and an outer membrane. In addition, bacterial cells may secrete polysaccharides that make a protective extracellular capsule on the surface of the cell.

The relatively strong and inert cell wall of eubacteria efficiently restricts the passage of macromolecules. In addition, bacterial cells do not have endocytic-like uptake systems, which are commonly utilized by eukaryotic viruses to gain access into the host cell. These features of the host strongly influence the mechanism employed by bacterial viruses to gain access into the host cytoplasm. In fact, the capsids of most bacteriophages are never internalized into the host cell; only the viral genome with some necessary protein factors is delivered across the host envelope.

Virions as a Genome Delivery Devise

Virions represent an extracellular form of the virus. It is a vehicle, which allows the virus to resist the harsh environment outside the cell. In addition to its protective nature, the main task of the virion is to recognize the host and to deliver the viral genome with necessary accessory factors to the new host cell. The mechanism of the genome delivery is typically reflected in the structure of the capsid (see below).

The nature of the viral genome influences the mechanisms of virus entry. Viruses that have genomes which cannot be expressed using the enzymatic apparatuses of the host, need to also bring viral polymerases into the host cell. This applies to all viruses having dsRNA or negative-sense ssRNA genomes. Regardless of the type of the genome, many viruses deliver some accessory protein factors inside the host. These are required in the early stage of the infection, prior to the viral genome expression, either to complete the entry process or for successful genome replication and expression.

Host Recognition

Host cell recognition by viruses is a highly specific process. Basically, all bacteriophages have, on their exterior surface, some protein that binds to a receptor molecule exposed on the surface of a susceptible cell. The receptor-binding proteins are often localized in the vertices of the

icosahedral virions or the tips of the helical virions. In tailed bacteriophages the initial recognition is carried out by the fibers that are connected to the distal end of the tail (**Figure 1**(**a**)). The specific recognition leads to irreversible structural rearrangements in the virion components; the viral receptor-binding complexes overcome an energy barrier and fold into a minimal energy state. These conformational changes lead to more tight attachment and eventually trigger the entry process. The rigid structure of the virion is destabilized so that the genome delivery can be accomplished. The icosahedral capsids of bacteriophages seldom disassemble completely; only the structures at the vertices become labile making openings for genome release.

Many bacteriophages, including icosahedral ssRNA bacteriophages (e.g., MS2, Qβ), filamentous ssDNA bacteriophages (e.g., Ff, as M13, fd, and fl), and enveloped dsRNA phage (ϕ6), utilize a bacterial pilus as their primary receptor. The pilus enables efficient capture of the virion at a distance from the cell surface, and the retraction of the pilus translocates the bound phages to the host envelope (**Figure 1**(**b**)). This allows phages to get access to the cell surface regardless of the polysaccharide capsule, which could restrict the easy access to the cell surface. Some phages (e.g., K1-5, K5, K1E), however, may also use the polysaccharide capsule as the initial site of recognition and binding. Typically, these phages have enzymatic activities associated with the virion for capsule degradation.

Other receptor sites for bacteriophages are lipopolysaccharides, various cell envelope and flagellar proteins, as well as cell-wall carbohydrates. The tailed phages infecting Gram-negative bacteria use either the lipopolysaccharide moieties (e.g., T2, T4, T7) or envelope proteins, such as porins and transporters (e.g., PP01, T1, T5, λ) as their receptors, while phages infecting Gram-positive bacteria typically attach to the cell-wall teichoic acids. Membrane proteins or peptidoglycan moieties rarely are used as attachment sites for bacteriophages infecting Gram-positive bacteria.

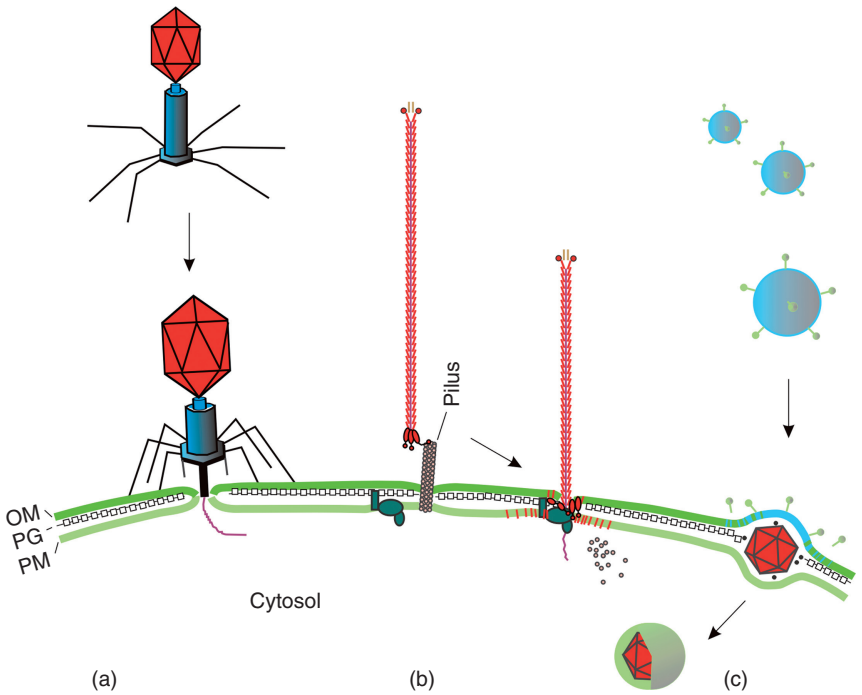

Figure 1 Schematic presentation of the main entry strategies utilized by bacterial viruses. OM, outer membrane; PG, peptidoglycan; PM, plasma membrane. (a) Genome delivery through an icosahedral vertex; given example is a phage with long-contractile tail from the family *Myoviridae* (e.g., T4). Primary interaction between the phage and the host cell is mediated by the tail fibers (black). Contraction of the tail sheath (blue) facilitates the penetration of the cell envelope. The viral genome (purple) is released from the head (red) of the phage virion through the tail tube (black) into the host cytosol. The protein capsid remains outside the cell. (b) Dissociation of filamentous phage capsid at the cell envelope. The receptor binding protein located at the tip of the helical virion interacts with the bacterial pilus. Pilus retraction brings the virion on the cell surface enabling interaction with the co-receptor molecule (green). The viral genome (purple) is released into the host cytosol as the virion proteins are inserted into the plasma membrane. (c) Penetration of the nucleoprotein complex of an enveloped dsRNA virion. The viral spike proteins (green) on the virion surface mediate the interaction between the host and the virion. Fusion between the host outer membrane and phage envelope (blue) takes place leading to the mixing of host and viral lipids. The nucleoprotein assembly (nucleocapsid; red) released into the bacterial periplasm penetrates the peptidoglycan network with the aid of a lytic enzyme (black) located on the nucleocapsid surface. Subsequently, the host plasma membrane is penetrated via an endocytic-like process.

Cell-Wall Penetration

The virions of many bacteriophages contain peptidoglycan-hydrolyzing enzymes. These are specialized proteins that locally and temporarily disrupt the peptidoglycan network, thus allowing the penetration of the cell wall. Similar enzymes are also involved in the release of progeny phages from the host cell at the end of the infection cycle. However, when assembled into virions, they likely have an active and crucial role in the entry process.

The lytic activity of virion-associated peptidoglycan-hydrolyzing enzymes is stringently controlled to ensure localized openings in the cell wall. This allows maintaining cell integrity, which is essential for successful production of progeny viruses during the infection cycle. For this reason such enzymes are tightly incorporated into the virus particle. The peptidoglycan-hydrolyzing enzymes of tailed bacterial viruses are often associated with the tail structures or, in the case of some short-tailed phages (e.g., T7), with internal head proteins that are ejected at the beginning of the infection cycle. Icosahedral dsDNA phages with internal membrane and no tail (e.g., PRD1, Bam35) as well as the enveloped dsRNA phage $\phi 6$ also possess peptidoglycan-hydrolyzing enzymes in their virions (see below; **Figure 1**(**c**)).

The most common cell-wall-degrading enzymes found in bacteriophage virions are lysozymes and lytic transglycosylases. Both lysozymes and lytic transglycosylases cleave the same glycosidic bond between *N*-acetylmuramic acid and *N*-acetylglucosamine units of the glycan strands. The end product of lysozyme is a disaccharide with reducing end of *N*-acetylmuramic acid, whereas that of lytic transglycosylase is a disaccharide containing a ring structure (anhydromuramic acid).

Not all phages have specialized enzymes in their virions for the penetration of the host cell wall during entry. These phages rely on preexisting channels within the host envelope. This applies to bacterial viruses with ssDNA and ssRNA genomes. For example, infection of filamentous ssDNA phages absolutely depends on a protein complex assembled in the bacterial plasma membrane spanning the peptidoglycan layer (**Figure1**(**b**)).

Genome Delivery Mechanisms of Phages

In general, entry strategies of bacterial viruses fall into three main categories: (1) genome delivery through an icosahedral vertex, (2) virion dissociation at the cell envelope, and (3) virion penetration via membrane fusion and endocytic-like event (**Figure 1**). All known tailed dsDNA phages (e.g., T4, T5, T7), dsDNA phages with an internal membrane (tectiviruses), as well as icosahedral ssDNA and ssRNA phages deliver their genome through a genome delivery apparatus located at one of the capsid vertices (**Figure 1**(**a**)). Capsids of filamentous phages and membrane-containing phage PM2 disassemble completely at the cell envelope (**Figure 1**(**b**)), whereas the enveloped dsRNA bacterial viruses utilize a unique membrane fusion-type uncoating at the outer membrane and virus subparticle internalization through the plasma membrane (**Figure 1**(**c**)).

Icosahedral Tailed dsDNA Bacterial Viruses

The tailed dsDNA bacteriophages use the tail structure as a genome delivery devise (**Figure 1**(**a**)). The tail is a protein tube of various length and complexity attached at one of the vertices of the icosahedral head. During the entry process the viral genome enclosed within the head travels through the tail into the host cell. Despite the numerous types of tailed bacterial viruses, they all possess one of the following three types of tails: long contractile, long noncontractile, or short noncontractile tail. The type of tail serves as the main criterion for classification of tailed bacteriophages and also influences the genome delivery mechanism.

The contractile tail which is common for members of the family *Myoviridae* is a complex, long tube assembly surrounded by a sheath that is terminated by a base plate typically decorated with terminal tail fibers (**Figure 1**(**a**)). The tail fibers act as sensor to detect the host bacterium. Interaction between the tail fibers and their surface receptors leads to conformational changes in the base plate and subsequent irreversible adsorption of the virus on bacterial cells. This triggers contraction of the tail sheath, which then drags the base plate along the tail tube making the tube protrude from the base plate (**Figure 1**(**a**)). Subsequently, the tail tube penetrates the cell envelope and phage DNA is released into the cell through a transmembrane channel made from viral proteins, host proteins, or a combination of both. The force required for penetration is associated with the contraction of the tail sheath. The peptidoglycan-hydrolyzing activity present in the tail tube facilitates the penetration of the peptidoglycan layer. Some viral proteins enter the cell with the phage DNA in order to protect it from host exonuclease activities and are implicated in the early stages of phage genome transcription.

The bacteriophages of the family *Syphoviridae* have long noncontractile tails. The noncontractile tail is composed of a relatively flexible tube ending with a tip (or straight fiber) and few tail fibers attached to the tube. In contrast to myoviruses, tails of syphoviruses do not possess a contractile sheath and therefore do not contract during DNA ejection. Nevertheless, the long noncontractile tail undergoes considerable conformational changes, which occur after primary interaction with the host cell. These conformational changes mostly concern the distal part of the tail (straight fiber). The straight fiber

penetrates the cell envelope and concomitantly shrinks in length while it increases in diameter. This signals the DNA to be released from the head of the virus. The straight fiber of the tail provides the channel for DNA penetration through the host cell envelope. Alternatively, viral DNA travels through a pre-existing pore within the host envelope, as many bacteriophages with noncontractile tails adsorb to channel forming protein complexes such as porins and transporters.

Members of the family *Podoviridae* have short noncontractile tails decorated with tail fibers. Tail fibers are responsible for host recognition and binding. Most of these viruses bind to the lipopolysaccharide of the outer membrane of Gram-negative bacteria. In contrast to the long tails of myo- and syphoviruses, the tails of podoviruses are too short to span the host cell envelope. After tail fiber attachment to lipopolysaccharide, several proteins are ejected from the virion. In the intact virion these proteins either form the internal core structure of the head or are located in the tail. Proteins ejected from the virion are involved in the formation of the channel across the cell envelope, thus extending the short tail and allowing the phage genome to travel from the virion into the cytoplasm.

Icosahedral dsDNA Bacterial Viruses with an Internal Membrane

The internal membrane of membrane containing dsDNA bacteriophages plays an important role during the entry process. According to the genome, the icosahedral membrane containing dsDNA phages fall into two families, *Tectiviridae* with the type member PRD1 and *Corticoviridae* with the only member PM2. The genome of tectiviruses is a linear dsDNA molecule with terminal proteins attached to the 5′-end, whereas the PM2 genome is a highly supercoiled circular dsDNA molecule. Obviously, these viruses use different strategies to deliver their genomes into the host cell.

Icosahedral dsDNA bacterial viruses with an internal membrane from the family *Tectiviridae* (e.g., PRD1) attach to the host cell receptor via a spike protein. The receptor structure for tectiviruses infecting Gram-negative cells is encoded by a multiple drug resistance conjugative plasmid. Specific interactions between the phage and the host induce dissociation of the spike complex from one of the capsid vertices and subsequent formation of a pore in the viral capsid. The internal membrane is transformed into a tubular tail-like structure, which protrudes from the capsid through the pore and penetrates the outer layers of the host cell. The rigid protein capsid stays intact outside the cell. Two lytic enzymes are associated with the virion (membrane) and function during the peptidoglycan penetration. A current model suggests that the viral integral membrane fuses with the host plasma membrane, thus connecting the cytoplasm with the interior of the viral membrane leading to delivery of the viral genome into the host cytoplasm. The members of the family *Tectiviridae* that infect Gram-positive bacteria (e.g., Bam35) attach to the host cell peptidoglycan structure. The internal membrane of these viruses also transforms into a tubular structure suggesting a similar mechanism for DNA entry into the host cell. The membrane tube of tectiviruses forms a channel for DNA translocation and thus is a counterpart to the tails of dsDNA bacteriophages discussed above.

Bacteriophage PM2 (*Corticoviridae*) infects Gram-negative marine bacteria from the genus *Pseudoalteromonas*. It has a circular dsDNA genome. The internal membrane of PM2 does not transform into a tubular structure in contrast to the internal membranes of tectiviruses. Instead, the capsid of the virus completely dissociates on the cell surface and the lipid core faces the host's outer membrane. The viral membrane most likely fuses with the bacterial outer membrane delivering the highly supercoiled dsDNA genome into the periplasm, from where it travels to the host cytosol.

Pleomorphic dsDNA Bacterial Viruses

The quasi-spherical virions of pleomorphic dsDNA bacterial viruses (*Plasmaviridae*) are nucleoprotein complexes within a lipid-protein membrane. The only classified member of the family *Plasmaviridae* is Acholeplasma phage L2. Acholeplasma are wall-less bacteria; thus, the phage adsorbs directly on the plasma membrane. It is assumed that adsorption leads to fusion of viral and host cell membranes resulting in entry of the nucleoprotein complexes into the cell.

Icosahedral ssDNA Bacterial Viruses

The icosahedral ssDNA bacterial viruses of the family *Microviridae* infect either free-living enterobacteria (e.g., ϕX174, G4, and α3) or obligate intracellular parasites lacking a cell wall, like chlamydia (e.g., Chp2) and spiroplasma (SpV4).

Icosahedral ssDNA bacterial viruses infecting free-living enterobacteria contain large spike complexes at the vertices of the virion. The spike complex is composed of five major spike proteins (G in ϕX174) and one minor spike protein (H in ϕX174) located at the spike apex. These spikes are responsible for the phage binding to the host cell, as well as for ejection of the ssDNA genome into the host cytoplasm. Bacteriophages infecting free-living enterobacteria adsorb to the lipopolysaccharide structures of the cell's outer membrane. Although microviruses are tail-less, they may follow an entry pathway similar to that of tailed phages (e.g., T4). Initially, ϕX174-like viruses adsorb reversibly to the cells. This is

analogous to the interaction of the tail fibers of tailed phages with the host cell. After reversible adsorption, which allows detection of the host bacterium, follows the irreversible adsorption. Virus binding to a suitable lipopolysaccharide induces conformational changes in the spike proteins and leads to DNA release from the viral capsid. Similarly to the tail of tailed phages, the major spike proteins constitute a channel through which the ssDNA travels into the host cytosol. The minor spike protein penetrates through the host plasma membrane along with the viral DNA. The viral capsid lacking DNA and one of 12 minor spike proteins remains outside the cell.

Large spike complexes are not present in the virions of phages that infect parasitic bacteria. Instead, they have elaborate viral coat protein protrusions on the threefold axis of symmetry not seen in the ϕX174-like viruses. These protrusions are likely responsible for the receptor recognition. Bacteriophages infecting parasites mostly use protein receptors present in the plasma membrane of wall-less bacteria.

Filamentous ssDNA Bacterial Viruses

Filamentous ssDNA bacterial viruses (family *Inoviridae*) mostly infect Gram-negative bacteria. Usually, they utilize the sites of bacterial envelope where outer and inner membranes are in close proximity. The protein complexes functioning as co-receptors are preferentially localized at these sites of the cell envelope.

The receptor-binding protein of filamentous bacteriophages is a minor coat protein (pIII in Ff phages) located at one end of the extended phage particle (**Figure 1(b)**). At the beginning of the infection process this protein binds to the tip of the bacterial pilus. Bacterial pilus is a complex assembly immobilized in the bacterial plasma membrane that spans the periplasmic space and protrudes through the outer membrane (**Figure 1(b)**). Pili are able to retract when they bind to the solid surface and are used for bacterial motility. Upon phage adsorption the pilus rapidly retracts bringing the phage particle through the outer membrane close to its co-receptor, a protein complex (TolQRA for Ff phages) located in the inner membrane and periplasm of the bacterial cell envelope (**Figure 1(b)**). Virus adsorption to the primary receptor (pilus) uncovers the co-receptor-binding domain in the receptor-binding protein of the virion. This allows the interaction between the receptor-binding protein of the virus and the co-receptor to proceed, thereby anchoring the virion to the bacterial plasma membrane. This triggers insertion of adjacent major coat proteins of the filamentous phage particle into the bacterial plasma membrane leading to uncoating of the virion and ssDNA translocation into the host cytoplasm (**Figure 1(b)**). The uncoating of the virion and genome translocation both require the functional co-receptor complex, which is involved in the formation of the channel for DNA traveling through the peptidoglycan and the plasma membrane.

Icosahedral Enveloped dsRNA Bacterial Viruses

The dsRNA bacteriophages (family *Cystoviridae*) have a unique entry mechanism among bacteriophages. As other dsRNA viruses, bacteriophages with a dsRNA genome deliver their genome within a large protein capsid, which protects the enclosed dsRNA genome throughout the infection cycle. Internalization of large nucleoprotein complexes into bacterial cells is rare. The protein capsid of dsRNA bacterial viruses, however, penetrates the host plasma membrane via a mechanism similar to endocytic entry of animal viruses (**Figure 1(c)**).

The virion of dsRNA bacteriophages contains three structural layers that sequentially assist in the penetration of the host outer membrane, the peptidoglycan layer, and the plasma membrane. The spikes protruding from the virion surface are involved in the receptor recognition and binding (**Figure 1(c)**). The dsRNA bacteriophages adsorb either to a bacterial pilus (e.g., ϕ6), which then retracts, or to polysaccharide (e.g., ϕ13). After phage adsorption at the outer membrane, the viral envelope fuses with the host membrane, thus uncoating the virion and placing the resulting viral nucleoprotein complex (or nucleocapsid) into the periplasm (**Figure 1(c)**). The fusion between the viral envelope and bacterial outer membrane is driven by the transmembrane proteins of the viral envelope whose fusogenic properties are activated after virus adsorption. The lytic enzyme of the virus located between the envelope and nucleocapsid locally digests the host cell-wall peptidoglycan, thereby allowing the nucleocapsid to reach the plasma membrane (**Figure 1(c)**). Eventually, the nucleocapsid penetrates the plasma membrane via an endocytic-like route. This involves the formation of the plasma membrane curvature at the contact site resulting in an intracellular vesicle, which then pinches off from the plasma membrane (**Figure 1(c)**). The transcriptionally active viral particle is released from the vesicle into the host cytosol.

Icosahedral ssRNA Bacterial Viruses

All of the known icosahedral ssRNA phages (e.g., MS2, Qβ, GA, family *Leviviridae*) are pilus specific and utilize bacterial pili as attachment site. The virions of icosahedral ssRNA phages contain a single attachment protein (or maturation protein), which carries out the initial interaction with the host pilus. The attachment protein is covalently linked to both ends of the genomic ssRNA. In addition, this protein is partially exposed on the capsid surface likely forming one of the capsid vertices. Virus adsorption initiates the cleavage of the attachment protein

into two fragments and later dissociation of those fragments from the viral capsid. As the pilus retracts into the cell, the attachment protein fragments together with the genomic ssRNA are pulled inside the host cell. The empty capsid remains outside the cell.

Bacteriophages with ssRNA genomes do not possess the peptidoglycan-hydrolyzing enzymes present in many other bacterial viruses which facilitate the peptidoglycan penetration during the entry process. Instead, ssRNA phages rely on the host cell pilus assembly to reach the cytoplasm.

Energetics

The viral genome transport across the host membrane is not a passive process. The force required for cell envelope penetration comes from different sources. As discussed earlier, phages with long contractile tails gain energy from the contraction of the tail sheath. This powerful process allows viral DNA to pass the host membrane in a very short time (e.g., 30 s for T4). Another type of energy comes from the pressure inside the viral capsid, which often is very high: In the capsids of dsDNA bacteriophages, the pressure may reach 50 atm (~5MPa)! This internal pressure of the virion, built up during DNA packaging, likely facilitates DNA ejection from the capsid during the initial stages of genome delivery.

The viral genome translocation may also be dependent on different host cell activities. The genome of T7 bacteriophage is pulled into the cytoplasm first by the host RNA polymerase and then by the RNA polymerase encoded from the phage genome. The retraction of bacterial pili and the transfer of the virus particles along the pili also depend on the cellular energy. Also, in many cases viral genome translocation requires membrane potential, which might provide energy to move DNA or RNA, stabilize a transmembrane channel, or regulate the genome translocation process.

Glossary

Chromosome The physical DNA or RNA molecule present in the virion and containing the information of the genome. The chromosome can differ from the genome by, for example, having a terminal repetition of part of the genomic sequence or being circularly permuted relative to other chromosomes in the population.

Genome The totality of the genetic complement of a virus. The genome is a conceptual object usually expressed as a sequence of nucleotides.

Homologous Having common ancestry. Homology of two sequences is often inferred on the basis of a high percentage of identity between the sequences, but homology itself is either present or not and is not expressed as a percentage.

Novel joint A novel juxtaposition of sequences in a genome resulting from a nonhomologous recombination event.

Bacteriophage Evolution

Bacterial viruses ('bacteriophages' or 'phages' for short) have probably been evolving for 4 billion years or more, but it is only in recent years that we have come to a relatively detailed view of the genetic mechanisms that underlie phage evolution. Phages do not leave fossils in the conventional sense, but the sequences of phage genomes contain more detailed information about how the phages have evolved than any conventional fossil has. Because of the importance of sequence, our understanding of phage evolution has increased dramatically as more phage sequences have become available over the past few years. Even more important than the individual sequences, however, is the fact that we have multiple genome sequences that we can compare to each other. It is in such comparisons of different genomes that we see the unmistakable signatures of past evolutionary events, which would be completely invisible in an examination of a single genome alone.

Most of the work on phage evolution has addressed evolution of the double-stranded DNA (dsDNA) tailed phages, the members of the order *Caudovirales*, and most of the discussion here deals with that group. Toward the end of the article, we will consider evolution of other groups of phages as well as recent evidence suggesting deep evolutionary connections between some of the bacteriophage groups and viruses that infect members of the Eukarya and Archaea.

The Tailed Phage Population

Nothing in phage evolution makes sense except in the light of what we have learned about the nature of the global population of tailed phages. The most remarkable fact is that the size of the population is almost incomprehensibly large – a current estimate is that there are about 10^{31} individual phage particles on the planet. To give a feeling for the magnitude of this number, if these phages were laid end to end, they would reach into space a distance of ~200 million light years. This is apparently a very dynamic population; ecological studies of marine viruses suggest that the entire population turns over every few days. To replenish the population would then require about 10^{24} productive infections per second on a global scale. Each such infection is an opportunity for evolutionary change, either by mutation during replication or by recombination with the DNA in the cell, which will almost always include DNA of other phages in the form of resident prophages. At a lower frequency, cells may be co-infected by two different phages, affording a different opportunity for genetic exchange. As described below, the evolutionary events that are inferred from genome sequence comparisons include extremely large numbers of improbable events, and the only way these events could have given rise to the existing phage population is if they have had an extremely large number of opportunities to occur.

Evolutionary Mechanisms in the dsDNA Tailed Phages

The Nature of the Genomes

The genomes of the dsDNA tailed phages use DNA very efficiently, with typically about 95% of the sequence devoted to encoding proteins. Spaces between genes can often be identified as containing expression signals such as transcription promoters or terminators. Genes are typically arranged in groups that are transcribed together. The specific types of genes in a genome, their numbers, and how they are arranged along the DNA are all highly variable among phages. Genome size is also variable, with the smallest known phages in this group having genomes of about 19 kbp and about 30 genes and the largest consisting genomes of 500 kbp and nearly 700 genes.

Types of Evolutionary Changes

Comparisons of genome sequences between phages reveal the sorts of changes in the genome sequence that in aggregate constitute phage evolution. The first of these is point mutation, in which one base pair is substituted for another. The number of point mutational differences seen between two homologous sequences varies from none to so many that our ability to detect any residual similarity of the sequence, often measured at the more sensitive level of the encoded amino acid sequence, has vanished. The amount of difference between two sequences due to point mutation is a function of how long it has been since they diverged from a common ancestral sequence, because such differences accumulate progressively over time. In practice, however, it is an unreliable measure of time for a number of reasons: we do not know the mutational rates for phages in a natural setting, we do not know that those rates have been constant over evolutionary time, and different genes accumulate changes at different rates because any mutations that are detrimental to the function of the encoded protein will be lost from the population by natural selection, and different proteins have different tolerances for mutational changes in their amino acid sequences.

The other major type of evolutionary change to a genome is DNA recombination. Particularly important is 'illegitimate' or 'nonhomologous' recombination, in which two different DNA sequences are joined together to form an association of sequences that did not exist before, known as a 'novel joint'. Nonhomologous recombination can join parts of two or more genomes into one

new genome; it can also cause deletion or inversion of a sequence within a genome by mediating recombination between two sequences in the genome. Nonhomologous recombination can in principle – and, it appears, also in practice – produce virtually any novel joint that can be imagined. The results of laboratory experiments have shown that homologous recombination happens many orders of magnitude more frequently than nonhomologous recombination. Unlike nonhomologous recombination, homologous recombination does not leave a novel joint that can be detected in analysis of the sequence, but it has the potential to reassort any flanking novel joints, bringing them and their associated sequences together in new combinations and providing a mechanism for them to move rapidly through the population.

Genome Comparisons

There is typically nothing in a single phage genome sequence, viewed in isolation, that reveals the presence of changes in the phage's evolutionary past, of either mutational or recombinational origin. When multiple genomes are compared, a wealth of differences corresponding to such changes is revealed. **Figure 1** illustrates a comparison for a group of four rather similar genomes of phages infecting enteric bacterial hosts. The physical gene map shown is that of *Escherichia coli* phage HK97, and the histograms indicate the locations of sequences in the other phages that match HK97. It is apparent that the genome sequences match each other in a patchwork fashion, and the parts of the sequence that match the HK97 sequence are different for the three phages. In other words, the genomes are genetic mosaics with respect to each other. In a pairwise comparison of genomes, the transitions between where sequences match and where they do not are abrupt, even when they are examined at the level of the nucleotide sequence. This implies that there have been nonhomologous recombination events in the ancestry of the phages, creating novel joints in the resulting recombinant phages. These novel joints are detected when they are compared with a sequence that did not suffer that particular recombination event. In the comparisons shown in **Figure 1**, there is evidence for about 75 ancestral nonhomologous recombination events, occurring in either the ancestry of HK97 or in that of one of the three phages being compared. It is worth noting that this probably underestimates the number of such events, because any novel joints that lie in the common ancestry of all these phages would not have been detected.

A striking feature of the novel joints in the sequence revealed by such genome sequence comparisons is that they fall predominantly at gene boundaries. While some are precisely at the gene boundaries, some also fall in the middle of spaces between genes or even a few codons into the upstream or downstream gene's coding region. More rarely, we can see novel joints in the interior of a gene's coding region. In the case of some such genes for which the encoded proteins are well characterized, the novel joints in the DNA sequence fall at a position corresponding to a domain boundary of the protein. Another feature of the genome comparisons that extends across all the groups of phages examined to date is that there are clusters of genes that are never, or rarely, separated by nonhomologous recombination. These are typically genes whose protein products are known to function together, such as the genes encoding the structural proteins of the head.

A frequent consequence of nonhomologous recombination among viruses is the transfer of genetic material from the genomes of one viral lineage into the genomes of a different viral lineage, a process known as 'horizontal transfer' or 'lateral transfer' of genes. This is the process that gives rise to the mosaicism in the genomes discussed above. It also means that different parts of a genome may, and most often do, have different evolutionary histories. This last fact leads to an interesting and still unresolved difficulty for viral taxonomists. That is, attempts to represent the relationships among viruses by a hierarchical taxonomy, as is conventionally done, necessarily fail to capture the multiple different sets of hierarchical relationships displayed by the individual exchanging genetic modules, deriving from their different evolutionary histories. The viruses, of course, are unaware of human attempts to classify them and so are unaffected by the resulting controversies.

Evolutionary Mechanisms

When the mosaicism of phage genomes was first seen in DNA heteroduplex mapping experiments in the late 1960s, it was proposed that there might be special sites in the DNA, possibly at gene boundaries, that served as points of high-frequency nonhomologous recombination, either through short stretches of homology or through a site-specific recombination mechanism. This view was formulated as the 'modular evolution' model of phage evolution, in which it was proposed that exchange between genomes took place repeatedly at these special sites, leading to the observed mosaic relationship between genomes.

With the current availability of many more genomes and data at the level of nucleotide sequence, it has become clear that, while the mosaic results of phage evolution are much as described nearly 40 years ago, the mechanisms by which that state is achieved are fundamentally different than what had been proposed. That is, the observations are best explained by a model of rampant nonhomologous recombination among phage genomic sequences, with the sites of recombination being distributed, to a first approximation, randomly across the sequence with no regard for gene boundaries or other features of the sequence. Most recombinants produced this way will be nonfunctional

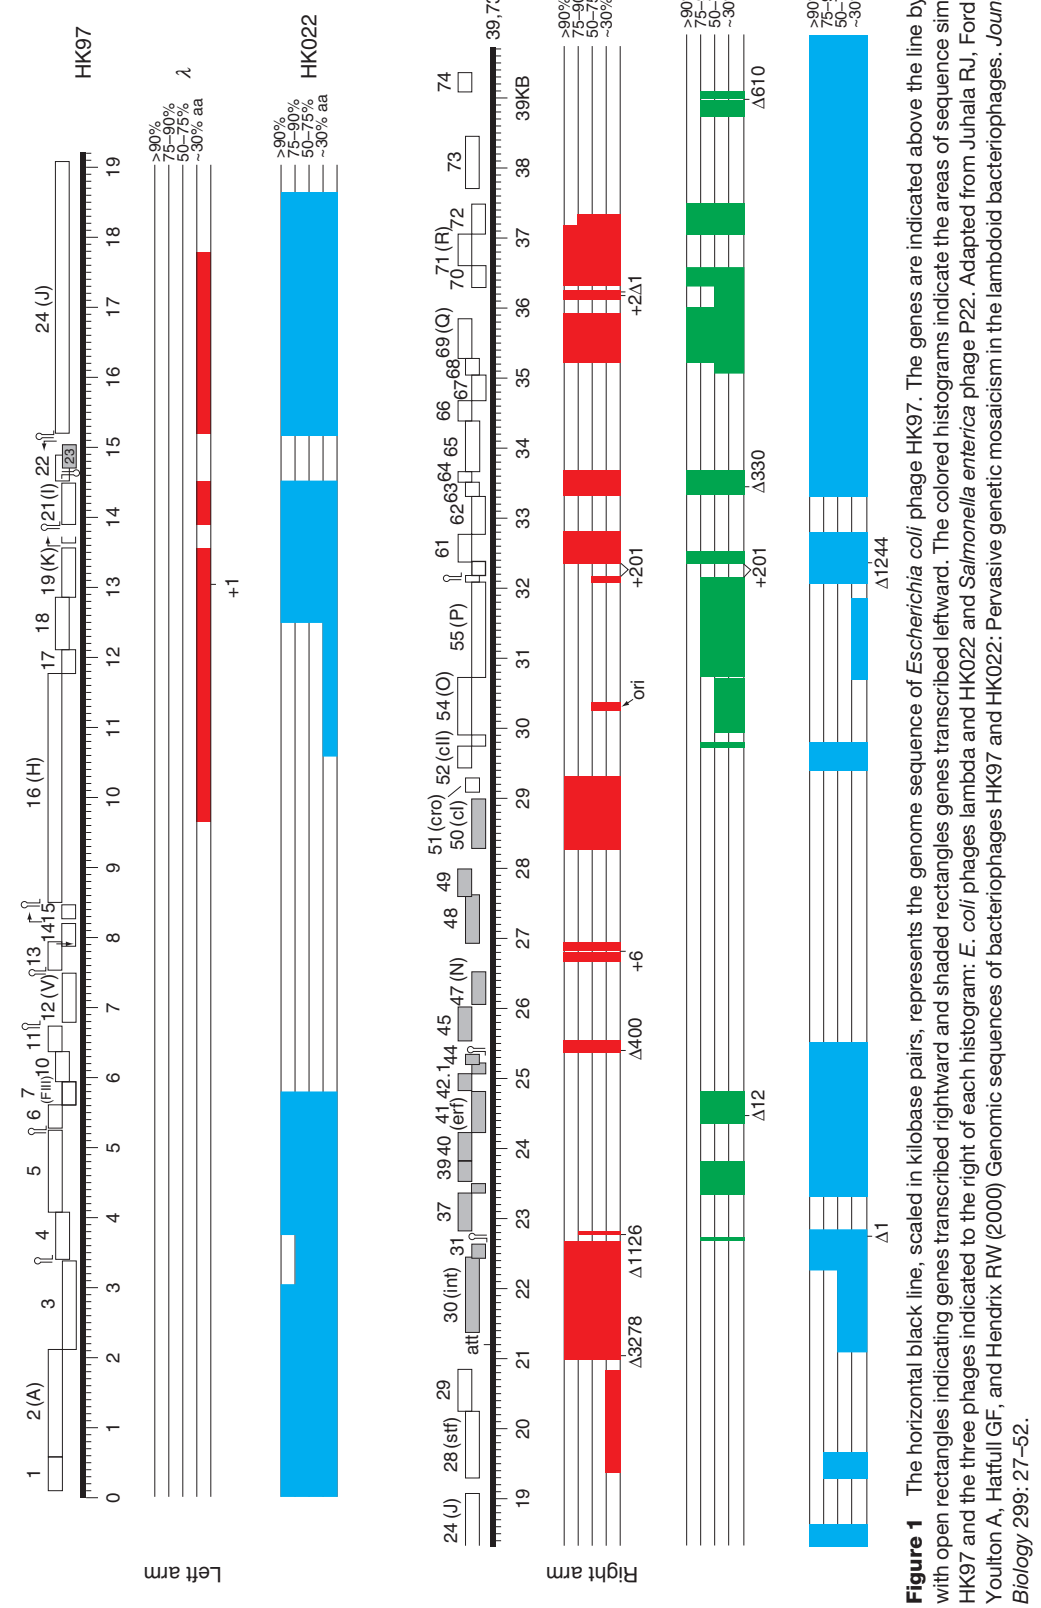

Figure 1 The horizontal black line, scaled in kilobase pairs, represents the genome sequence of *Escherichia coli* phage HK97. The genes are indicated above the line by rectangles, with open rectangles indicating genes transcribed rightward and shaded rectangles genes transcribed leftward. The colored histograms indicate the areas of sequence similarity between HK97 and the three phages indicated to the right of each histogram: *E. coli* phages lambda and HK022 and *Salmonella enterica* phage P22. Adapted from Juhala RJ, Ford ME, Duda RL, Youlton A, Hatfull GF, and Hendrix RW (2000) Genomic sequences of bacteriophages HK97 and HK022: Pervasive genetic mosaicism in the lambdoid bacteriophages. *Journal of Molecular Biology* 299: 27–52.

because, for example, they have glued together parts of two encoded functional proteins into a nonfunctional chimera. The tiny fraction of such recombinants that are fully functional and competitive in the natural environment will be those that have recombination joints where they do no harm, like at gene boundaries; the rest will be rapidly eliminated from the population by natural selection. We would also expect that two recombining genomes would not typically be lined up in register, and this would most often lead to nonfunctional recombinants. There are a few examples of genomes with short quasi-duplications that can be explained by a slightly out of register recombination event, supporting this supposition.

Nonhomologous recombination also has the potential to bring novel genes into a genome and to mediate large-scale reorganizations of genomes, as seen for example in *E. coli* phage N15 which has head and tail structural genes homologous to those of phage lambda and, in the other half of the genome, genes from a very different, apparently plasmid-like, source. Another example is the *Shigella* phage SfV, which has head genes in the phage HK97 sequence family and tail genes like those of phage Mu.

The entire process described above can be viewed as a classical Darwinian scenario in which tremendous diversity is generated in the population by a combination of point mutations and homologous and nonhomologous recombination, and the stringent sieve of natural selection acts to eliminate all but the fittest recombinants. The survivors have largely, though not entirely, lost the appearance of having been generated by what is essentially a random mutational process.

Evolution of Other Phage Types

Although most of the genome comparisons that have led to our current understanding of phage evolution have been carried out with the tailed phages, there has been some work done with other groups. The most extensive has been done with members of the families *Microviridae* and the *Inoviridae*, phages with small, circular single-stranded DNA (ssDNA) chromosomes, typified by the well-studied *E. coli* phages ϕX174 and M13. For both of these groups there is evidence for horizontal exchange of sequences, as in the tailed phages, but it is quantitatively much less prominent than what is seen in the tailed phages. There are several differences between the tailed phages and these two groups of smaller phages, some or all of which may contribute to the differences in evolutionary outcomes seen between them. These include 10- to 100-fold differences in the sizes of the genomes and the fact that the members of the *Microviridae* and *Inoviridae* do not encode recombination functions, among others.

Another study looked at evidence for evolutionary change among members of the family *Cystoviridae*, a group of phages with a double-stranded RNA (dsRNA) genome, divided into three physical segments. Comparisons among environmentally derived genome sequences showed no evidence for recombinational exchange within the segments but clear indications of reassortment of the segments. Thus it appears that evolution in this group of viruses achieves the same general outcome as evolution of the tailed phages, namely horizontal exchange of genetic modules, but by a very different mechanism. Analogous horizontal exchange by reassortment of the segments of a segmented genome has been extensively characterized in the influenza viruses, a group of animal viruses with a single-stranded RNA (ssRNA) genome of eight segments.

Deep Evolutionary Connections

Although there are some genes that are found in all tailed phages – for example, genes encoding the major capsid protein – these are very diverse in sequence. This diversity is sufficiently great that it is not possible, on the basis of their sequences, to group them into a single sequence family, at either the DNA or the protein sequence levels. Thus the subsets of capsid protein sequences that share demonstrable sequence similarity may represent independent nonhomologous lineages of capsid proteins, or alternatively they may all be part of the same lineage but have diverged in sequence to the point that in many cases no surviving sequence similarity can be demonstrated. However, recent structural work on the polypeptide folds of capsid proteins appears to be extending our analytical reach farther back in evolutionary time and giving a resolution to this question. High-resolution X-ray structures of the capsid proteins of phages HK97 and T4 demonstrate that they have a common fold which might indicate common ancestry despite the absence of any surviving sequence similarity. Cryoelectron microscopic structures of phages representing two more capsid protein sequence groups, P22 and ϕ29, make a less rigorous but still convincing case that these capsid proteins also share in a common polypeptide fold and so are most likely part of the same lineage. Remarkably, a similar experiment on (the animal virus) herpes simplex virus argues that the shell-forming domain of its major capsid protein also shares the tailed phage capsid protein fold and so may be part of the same lineage.

A similar and more completely documented case for a virus lineage extending across the cellular domains of the hosts they infect can be made for a group that includes bacteriophage PRD1 (a member of the family *Tectiviridae*), archaeal virus STIV, and eukaryotic viruses adenovirus, PBCV1 (*Phycodnaviridae*), and mimivirus. This is again based on shared capsid protein folds, in this case an unusual double 'jellyroll' fold. Finally, there is compelling

structural similarity between the cystoviruses, the group of phages with segmented dsRNA chromosomes, and a characteristic double protein shell discussed above, and the reoviruses of plant and animal hosts.

The simplest interpretation of these observations, though not the only possible interpretation, is that there were already viruses resembling these different types of contemporary viruses prior to the divergence of cellular life into the three current domains. The different types of viruses in this view would have co-evolved with their hosts as the hosts divided into domains and descended to the present time, with in the end nothing to indicate their common origins except the shared structure of their capsid proteins. Whatever the truth of this matter, an important caveat to such an interpretation is that the evidence for common viral ancestries across host domains is at present based primarily on conserved properties of capsid proteins, and so any conclusions about common lineages, strictly speaking, only apply to capsid protein lineages. However, despite such reservations, the data make an intriguing though still tentative case that viruses resembling at least three groups of contemporary viruses had already evolved into forms something like those of contemporary viruses before the three domains of cellular life had begun to separate, ~3.5 billion years ago.

Glossary

Functional genomics The study of genes with respect to the role they play within biological processes.

High-throughput screening A method to efficiently test a large number of putative genes to identify candidates that may regulate a specific biological process.

Hypersensitive response A defense response in plants that initiates cell death to restrict the growth of pathogen.

Knockdown Reduction in the expression of a gene.

Knockout Complete inhibition of gene expression.

Reverse genetics Approaches used to define the function of a gene or sequence of DNA within the context of the organism.

T-DNA Transfer DNA from *Agrobacterium tumefaciens*, a vector routinely used for transforming plants.

Introduction

Virus-induced gene silencing (VIGS) is an RNA silencing-based technique used for the targeted downregulation of a host gene through the use of a recombinant virus. The term VIGS was originally coined to describe the phenomenon of recovery of a host plant from viral infection. Today, its usage is predominantly in reference to a tool for turning down host gene expression, especially in plants. In principle, a plant gene of interest can be silenced by infecting the plant with a viral vector that has been modified to express a nucleic acid sequence homologous to the host gene. Viral infection and synthesis of double-stranded RNA (dsRNA) viral replication intermediates initiate the innate RNA silencing or post-transcriptional gene silencing (PTGS) pathway, ultimately leading to the degradation of host transcript. The potency, specificity, and speed of PTGS have thus been harnessed to create an efficient gene knockout system. The ability of VIGS to rapidly initiate silencing and generate mutant phenotypes without the use of laborious transgenic approaches has

made it the tool of choice for characterizing genes, especially in plant species where conventional analytical techniques have had limited success.

PTGS and the Principle behind VIGS

The term virus-induced gene silencing was first used by A. van Kammen to describe the process by which some plants were able to recover from viral infection, coincident with the loss of viral RNA from the infected tissue. The recovery process was soon understood to be associated with the plant inherent RNA-silencing mechanism which is an evolutionarily conserved antiviral system. Most plant viruses are RNA viruses and produce dsRNA intermediates during replication. In contrast to host messenger RNA, the viral dsRNA is made up of relatively long stretches of complementary RNA strands. The host identifies these as foreign and triggers the RNA-silencing pathway. The plant recovery is thus the successful outcome of the actions of this surveillance system.

The phenomenon of RNA silencing, initially observed in plants where it was called PTGS, has since been known to operate in almost all eukaryotic species including fungi, worms, flies, and mammals. In fungi, the process is called quelling while in animal systems it is known as RNAi (RNA interference). In plants and other eukaryotes, the mechanism of RNA silencing of viruses is highly conserved. The dsRNA which is generally synthesized by a viral polymerase or in some cases a host-encoded RNA-dependent RNA polymerase is recognized and cleaved by Dicer, a ribonuclease III (RNase III)-like enzyme. This results in the production of 21–24 nt duplex molecules called short-interfering RNAs (siRNA's). In an ATP-dependent manner, the siRNA's are denatured and one strand is exclusively incorporated into a multi-subunit nuclease complex called the RNA-induced silencing complex (RISC). Within the RISC, siRNA serves as a guide to recognize and base pair with the homologous RNA (in this case the viral RNA), eventually leading to degradation of the target RNA. This occurs via an RNase H-like cleavage mechanism directed by the RISC. One of the key factors that make PTGS such a potent system of host defense is that once initiated, it can maintain the silencing effect by relaying a diffusible silencing signal throughout the plant. As the virus moves within the host tissue, those cells that have received the silencing signal are primed to recognize the viral RNA and initiate its degradation.

PTGS and its efficiency against viral genomes can be exploited to create recombinant viral vectors that serve as tools for gene silencing. Viruses carrying segments of host genes, when used to infect plants, would produce siRNA's specific to the host mRNA. RISC-mediated degradation of target host mRNAs would ultimately lead to downregulation of gene expression. The infected plant would thus have a phenotype similar to a loss-of-function mutant of the gene of interest. The efficiency of viruses in initiating silencing was first shown in plants infected with a recombinant tobacco mosaic virus (TMV) carrying a fragment of the plant gene *phytoene desaturase* (*PDS*), a regulator of carotenoid biosynthesis. Infected *Nicotiana benthamiana* plants showed degradation of the host PDS mRNA and resultant alterations in the pigment synthesis pathway led to significant photobleaching in the leaves. The potential of this gene knockout system was immediately recognized and has since been applied to more than ten plant species. The *PDS* gene now serves as the conventional gene used for testing the efficacy of a virus in inducing silencing (**Figure 1**).

The Development of VIGS as a Tool for Functional Genomics

Several VIGS vectors have been developed over the past 8 years (**Table 1**). The choice of VIGS vector plays a key role in efficient silencing and there are many factors to be considered when choosing the virus to be used for VIGS. Ideally, the virus must produce little or no symptoms during infection, thereby facilitating easy visualization and interpretation of the mutant phenotype. It must induce persistent silencing. Viruses with strong silencing suppressors are avoided since they can interfere with the establishment of silencing. It is advantageous to have infectious cDNA clones of the virus for cloning purposes and the virus must retain infectivity after insertion of foreign DNA. The virus should also show uniform spread, infect most cell types including the meristem, and preferably show a broad host range.

RNA Virus-Based Vectors

TMV, an RNA virus belonging to the genus *Tobamovirus*, was the earliest viral vector to be used for VIGS but the severity of symptoms in susceptible tissue and inability to invade the meristem limited its application. A PVX (potato virus X)-based vector produced milder infection symptoms but displayed a narrower host range and did not infect the growing points of infected plants. Tobacco rattle virus (TRV) was shown to overcome all these disadvantages and currently is the most widely used VIGS vector, especially in solanaceous hosts. It can infect all cell types including the meristem and so can be used to investigate the role of genes in early developmental processes. The silencing is more persistent when compared to other viral vectors and it is documented to infect a wide range of hosts.

TRV is a plus-sense RNA virus with a bipartite genome. RNA-1 encodes the viral replicase and movement

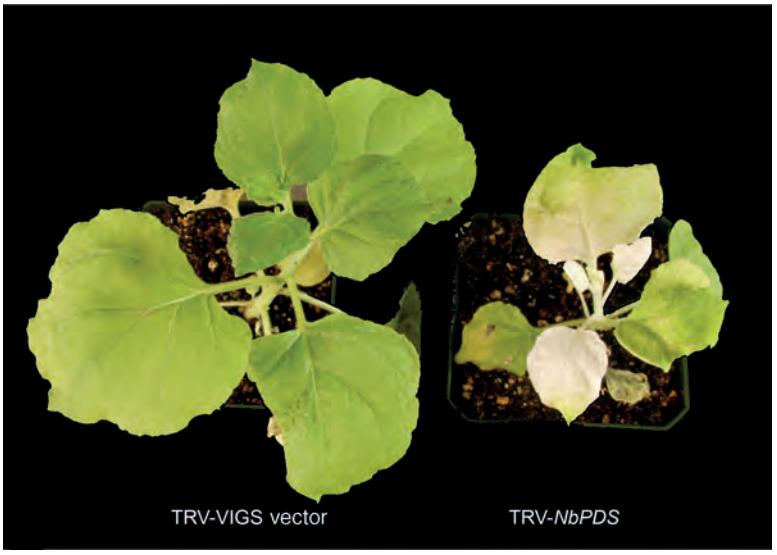

Figure 1 Silencing of the *PDS* gene (phytoene desaturase) in *N. benthamiana* using TRV-based VIGS system. *Nicotiana benthamiana* plants infected with the empty vector TRV-VIGS do not have a noticeable phenotype while TRV-*NbPDS*-infected plants show photobleaching, a hallmark of PDS silencing.

Table 1 Selected list of plant viruses used as VIGS vectors for gene silencing

Virus	*Genus*	*Host*	*Method of infection*
Tobacco mosaic virus	*Tobamovirus*	*N. benthamiana*	Inoculation of infectious viral RNA
Potato virus X	*Potexvirus*	*N. benthamiana,* potato	Inoculation of infectious viral RNA; agro-inoculation
Tobacco rattle virus	*Tobravirus*	*N. benthamiana, Arabidopsis thaliana,* tomato, pepper, petunia, potato, poppy	Agro-inoculation
Pea early browning virus	*Tobravirus*	Pea	Agro-inoculation
Satellite Tobacco mosaic virus (with helper TMV)	*Tobamovirus*	Tobacco	Inoculation of infectious viral RNA
Bean pod mottle virus	*Comovirus*	Soybean	Inoculation of infectious viral RNA
Tomato golden mosaic virus (TGMV)	*Geminivirus*	*N. benthamiana*	Microprojectile bombardment
Cabbage leaf curl virus (CaLCuV)	*Geminivirus*	*A. thaliana*	Microprojectile bombardment
African cassava mosaic virus (ACMV)	*Geminivirus*	Cassava	Microprojectile bombardment
Barley stripe mosaic virus	Hordeivirus	Barley, wheat	Inoculation of infectious viral RNA
Fescue strain of Brome mosaic virus (F-BMV)	Bromovirus	Rice, maize, barley	Inoculation of infectious viral RNA

proteins, while RNA-2 contains genes for the coat protein and two nonstructural proteins, one of which is needed for vector transmission. Since the latter two genes are dispensable for viral replication and spread in plants, RNA-2 could be modified to replace the nonstructural genes with a multiple cloning site for insertion of host-derived gene sequences. The host sequence to be inserted into the viral vector could theoretically be as small as 23 nt (the size of an siRNA) but in practice the ideal size range is between 300 and 1500 bp.

There are many ways of introducing the virus into the plant system and these include rubbing the plants with infectious viral transcripts or biolistic delivery. However, the most effective means appear to be incorporation of the viral cDNA into *Agrobacterium tumefaciens*-based plant transformation vectors (T-DNA vectors) under the control of constitutive promoters followed by infiltration of the *Agrobacterium* cultures into the host. This ensures not just ease in the inoculation procedure but also efficient transformation and high levels of viral RNA production within plant cells. For the TRV system, VIGS can be induced by simply mixing individual *Agrobacterium* cultures containing RNA-1 and modified RNA-2 and then co-infiltrating into young plants using a needle-less syringe. Alternatively, the cultures can also be vacuum-infiltrated or sprayed onto the plant.

The appearance of VIGS-related phenotype depends on a number of factors including the plant species used, the age of the plant, and environmental factors like temperature and humidity. Under optimal conditions in *N. benthamiana* plants, TRV-induced silencing phenotypes can be visualized as early as 1 week. TRV is also one of the few viruses that have been modified into a highly efficient cloning and expression system for use in large-scale functional genomics screens. One of the most useful features of TRV vectors is their ability to induce VIGS in a number of solanaceous hosts like *N. benthamiana*, tomato, potato, pepper, petunia, poppy (Eudicot species), and the model system *Arabidopsis thaliana* (family Brassicaceae).

A number of other viruses have been adopted for VIGS in species where TRV has not been efficacious (**Table 1**). For tobacco plants, researchers have developed the satellite virus-induced silencing system (SVISS), which is a two-component system that uses a modified satellite TMV (that acts as the inducer of silencing) and a helper TMV-U2 virus (that promotes viral replication). Most of the VIGS vectors thus far described have been designed for dicotyledonous species though a majority of the economically important food crops such as rice, maize, wheat, and barley are monocots. The RNAi machinery has been shown to function in monocots and hence research in recent years has focused on finding ideal monocot VIGS vectors. The hordeivirus barley stripe mosaic virus (BSMV) was the first virus adapted for VIGS in barley and subsequently applied to wheat. A specific strain of brome mosaic virus isolated from tall fescue (F-BMV) was cloned, characterized, and modified for use as a VIGS vector. F-BMV-based vectors were shown to effectively silence genes from rice, barley, and some cultivars of maize. The successful adaptation of VIGS technology in monocots will, in the future, aid in the functional characterization of genes in these otherwise recalcitrant systems.

DNA Virus-Based Vectors

DNA viruses belonging to the family *Geminiviridae* like tobacco golden mosaic virus (TGMV) and cabbage leaf curl virus (CaLCuV) have been successfully employed for silencing and serve as good alternatives to RNA viruses. CaLCuV was also the first VIGS vector to be used to knockdown gene expression in *Arabidopsis*. Geminiviruses are highly conserved in their genetic sequence and so, in theory, these viruses can be quickly adapted for VIGS based on information from one virus. Other beneficial properties of geminiviruses are that they are genetically more stable than RNA-based vectors, can invade meristematic tissue, and infect a wide range of plants including economically important crops. In fact, begomoviruses like African cassava mosaic virus (ACMV) and pepper huasteco yellow vein virus (PHYVV) have been successfully employed as VIGS vectors in cassava and pepper. As a caveat, it must be noted that most of the geminiviruses used so far appear to induce some symptoms of infection and thus care must be taken when interpreting VIGS phenotypes.

Applications of VIGS in Aiding Plant Gene Characterization

There have been numerous examples validating VIGS as an effective method for loss-of-function studies in plant systems. The preeminent use of this technique has been in studying plant–pathogen interactions, especially in deciphering plant defense pathways. Resistance against pathogens in many plants is dictated by the presence of specific *R* genes and each gene exclusively initiates defense against one race of a given pathogen. Numerous studies have used VIGS to study genes that are activated or regulated in *R* gene pathways. These include *N* gene-mediated resistance to TMV, *Rx1*-mediated resistance to PVX, *Mla13*-mediated resistance to powdery mildew, *Cf-4* regulated resistance to *Cladosporium fulvum*, and *Pto*-mediated resistance to *Pseudomonas syringae* in tomato. In some of these studies, cDNA libraries inserted into VIGS vectors were screened to identify genes that were essential for the *R* gene-activated hypersensitive response (HR) which is a hallmark of plant defense. These studies in parallel identified common components in disease resistance like the chaperone protein HSP90, mitogen-activated protein (MAP) kinase pathway proteins, regulators of the protein degradation pathway, and TGA and WRKY transcription factors. The use of VIGS has also aided in the identification of novel pathways that play a role in defense or pathogenesis. For instance, autophagy, an evolutionarily conserved programmed cell death response, was found to be important for limiting cell death induced during viral infection. Similarly, $P58^{IPK}$, a plant ortholog of the inhibitor of mammalian dsRNA-activated protein kinase (PKR), was shown to be recruited by TMV to maintain infectivity. While the function of PKR in defense has been well characterized in animal systems, this was the first study showing a role for this protein in plant viral pathogenesis.

Meristem invasion by viruses like TRV make them ideal for use in silencing genes that may be important for cell proliferation, tissue differentiation, and flower development. Studies on floral genes have mainly been limited to model systems like *Arabidopsis* and petunia, but with the advent of VIGS it is now possible to test floral homeotic genes in a wide range of hosts and analyze conservation or divergence of gene functions between species. As a case study, in solanaceous plants, the ortholog of *Arabidopsis* and *Antirrhinum* floral homeotic gene *AP3/DEFICIENS* was silenced and found to produce a phenotype similar to that seen in *Arabidopsis*. The TRV system was also used to

initiate VIGS in tomato fruits showing its potential in studying fruit development. An *N. benthamiana* cystein protease, calpain, was shown to play a key role in cell differentiation and organogenesis using the TRV-VIGS system. Similarly, the role of proliferating cell nuclear antigen (PCNA) was investigated with geminivirus-derived vectors. The primary advantage of using VIGS for such studies is not just that it expands the study of plant growth and differentiation into nonhost systems, but also that it overcomes problems of embryo lethality or sterility which would be unavoidable if true mutants of these genes were being studied.

Among its other applications, VIGS has been adopted for analyzing biosynthetic pathways (sterol synthesis and pigment synthesis), characterizing genes involved in stress response or hormone response, organelle biogenesis, and to look at transport of proteins within the cell (especially nuclear transport mediated by different importins).

Advantages of Using VIGS as a Tool for Functional Genomics

In plants, the conventional methodology for gene function analysis has been to use insertional mutagenesis to shut down expression of the gene of interest and study the consequence of its loss to the plant. The T-DNA plasmid of *Agrobacterium*, which is capable of inserting into the plant genome, has for a long time been one of the tools of choice for disrupting plant genes. An alternative approach has been to use transposons. While being powerful tools for reverse genetics, they came with a number of limitations. Laborious and time-consuming screens had to be carried out to search for T-DNA insertions or transposon tagged lines. Loss of genes essential in the early developmental stages led to embryo lethality while functionally redundant genes rarely showed a discernible phenotype when knocked out and so these genes could not be identified in screens. These techniques were also not amenable for genomic-scale studies because of the difficulty of achieving genome saturation and problems with multiple insertions. The advent of RNA-silencing technology meant that it was possible to disrupt the function of a specific gene by the introduction of gene-specific self-complementary RNA, also known as hairpin RNA (hpRNA). This process still required plant transformation and screening to identify silenced plants. Many of the constraints imposed by these methodologies have been overcome with the discovery of VIGS and its subsequent use a tool.

The biggest advantage with this technology is the short time needed to go from gene sequence to functional characterization of its knockdown. While screening for a potential T-DNA knockout would take at least a few months, with VIGS it can be scaled down to 2 weeks. Thus relationships between genes and phenotypes/functions can be established quickly. This factor alone has catapulted VIGS into one of the most widely accepted and popular tools for gene analysis. VIGS is not as labor intensive as the other techniques since it does not involve transformation of plant tissue. Application of the virus and induction of VIGS are easy, especially after incorporation of viral sequences into intermediate plant transformation vectors. VIGS can, in general, be induced at any stage during a plant's life cycle – thus it is still possible to characterize genes that may otherwise be lethal when knocked out during early stages of development. One can overcome redundancy by carefully choosing the gene sequence to be inserted into the viral vector so as to maximize (or minimize) the silencing of related genes. Many VIGS vectors can be used on multiple host species and this can prove useful for testing gene functions against different genetic backgrounds. These vectors have accelerated the characterization of genes in many nonmodel hosts like *N. benthamiana*, petunias, potato, soybean, and even poplars where conventional techniques achieved very limited success. Finally, as has been shown with TRV and PVX, VIGS vectors can be adapted for use in high-throughput functional genomic screens.

Limitations of VIGS

It must be noted that, like all other techniques, VIGS also has its limitations. Above all, it can only induce a transient silencing response. In almost all cases, we observe an eventual recovery of the host from the viral infection and subsequent replenishment of gene transcript levels. Due to the nature of the silencing phenomenon, even during the peak silencing stages, one cannot be assured of complete knockout of transcript levels. In spite of using weak or attenuated viruses, it is not possible to avoid some of the host gene expression changes that are associated with the viral infection and these factors must be taken into consideration while interpreting the results. Ideally, therefore, VIGS should be used in conjunction with or validated by other techniques of gene function analysis. The use of recombinant viruses also requires greater precautionary measures and care must be taken to avoid accidental transmission of the modified or infectious virus.

Conclusions

With the sequencing of numerous genomes completed or near completion, we have in our hands a vast amount of genetic data that is to be deciphered, genes that need to be characterized, and pathways that are to be elucidated. The need of the hour is for powerful functional analysis tools and in the last few years VIGS has proven to be the

breakthrough technology that aids in rapid and robust gene characterization. Plant gene analysis has traditionally been carried out in few model systems whose genomes have been sequenced and are also easily amenable to transformation techniques. VIGS is one of the few tools that can be applied on a broad spectrum of plants, since most plants are susceptible to viral infections. VIGS will therefore play a crucial role in promoting gene analysis in many nonmodel systems including those that have duplicated genomes or do not have a sequenced genome. A plethora of new viruses are being added to the list of VIGS vectors and it is exciting to note the addition of vectors for monocots like rice, wheat, and maize. Small grain cereals are among the world's most important food crops but gene discovery and annotation in these systems have been carried out on only a small scale mainly due to the lack of tools for reverse genetics. The adaptation of VIGS in monocots will therefore play an important role in gene analysis and annotation in these economically important crops.

Within the animal kingdom, RNA-silencing technology has been harnessed to carry out genomewide silencing screens. In human cells, *Drosophila*, and *Caenorhabditis elegans*, dsRNA or hpRNA's designed to systematically target a majority of predicted genes have been screened to identify novel players in cell growth, proliferation, and cell death. We now have all the tools necessary to carry out similar whole genome functional discovery studies in plants. The successful application of VIGS in two completed plant genome sequences, *Arabidopsis* and rice, opens up the possibility of carrying out systematic loss-of-function studies in these systems. Many plant genomes have been partially annotated in the form of expressed sequenced tags (EST) libraries, which serve as inventories of expressed genes. These EST libraries can also serve as ideal resources for use in VIGS-mediated high-throughput screening. In the postgenomics era, VIGS will prove to be a technique that will help accelerate the conversion of genomic data to functionally relevant information and contribute to our understanding of the molecular processes occurring within plants.

Virus Particle Structure: Nonenveloped Viruses

J A Speir and J E Johnson, The Scripps Research Institute, La Jolla, CA, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Nonenveloped viruses provide model systems for high-resolution structural study of whole virus capsids (and their components) and the principles of large-scale nucleoprotein tertiary and quaternary interactions. In many cases, they are relatively small, stable, and highly symmetric particles that can be purified as homogeneous samples in large quantities. These properties make them suitable for the techniques of X-ray crystallography, X-ray fiber diffraction, and cryoelectron microscopy (cryo-EM) combined with image reconstruction. Enveloped virus particles generally have greater flexibility and asymmetry, two features that inhibit application of high-resolution techniques.

The first crystal structures of intact virus capsids published in the late 1970s and early 1980s are examples of the simplest forms of replicating organisms. They were small, spherical, positive-sense single-stranded (ss) RNA plant viruses about 170–350 Å in diameter with $T = 1$ or $T = 3$ symmetry, which were easy to purify in gram quantities. By the mid- to late 1980s, the structures of small ssRNA animal viruses (poliovirus and the common cold virus, rhinovirus) and the intact, 3000 Å-long ssRNA helical tobacco mosaic virus (TMV) were also completed. The range of virus types, sizes, and complexity addressed by X-ray crystallography has grown significantly with advances in X-ray technology and computing. Detailed polypeptide and nucleic acid models have now been fitted

into data between 4–1.8 Å resolution. Crystal structures of 800 Å diameter virus capsids with $T = 25$ icosahedral symmetry have now been determined and show quaternary polypeptide interactions as intricate and varied as their biology.

Spherical particles larger than 800 Å in dimension have been studied by cryo-EM providing detailed images of some of the most complex structures ever visualized at high resolution. This technique is also readily applied to smaller viruses like those described above. Typical cryo-EM studies produce 15–30 Å resolution image reconstructions, but under ideal conditions sub-nanometer resolution can be obtained. The upper diameter limit for applying the cryo-EM technique to viruses is yet to be hit; however, with increased sample thickness (e.g., particle diameter), comes an increase in data collection and analysis restrictions. Currently, the two largest spherical virus structures determined with cryo-EM are the 2200 Å diameter PpV01 algae virus, that has an icosahedral protein shell with $T = 219$ quasi-symmetry, and the 5000 Å diameter mimivirus, found in amoebae, that has an icosahedral protein shell with estimated $T = 1179$ quasi-symmetry. While the PpV01 structure was determined at 30 Å resolution, the thickness of ice needed to embed mimivirus (7500 Å for shell + attached fibers) limited the image reconstruction to 75 Å resolution, which is the reason for the estimated T number. Thus, cryo-EM can provide detailed images of symmetrical virus particles of almost any size and is an increasingly valuable tool in virus structural studies.

In cases where capsid size or other factors prohibit obtaining near-atomic resolution data, structures of the individual proteins or their assembly products can be determined by nuclear magnetic resonance (NMR) and/or X-ray crystallography. Capsid subunit folds, nucleic acid-binding sites, and some details of quaternary structure can be gathered in this way. Exciting leaps in understanding virus capsid assembly, interactions, and dynamics have come from combining individual structures with cryo-EM particle images to build complete pseudo-atomic models for the larger, more-complex virus capsids. The combined approach generates discoveries that could not have been obtained from either method alone. This article highlights some of the important features of the more than 200 high-resolution nonenveloped virus structures determined to date.

The Building Blocks

The β-Barrel Fold

The earliest spherical virus capsid structures, both of animal and plant viruses, revealed a strikingly common fold for the structural subunits that continues to be found in new virus structures: the antiparallel β-barrel (**Figure 1**). It has been found mainly in icosahedral particles, but is also known to form the bacilliform particles of alfalfa mosaic virus (AMV). The barrel is formed by two back-to-back antiparallel β-sheets with a jelly-roll topology defining a protein shell approximately 30 Å thick. The β-barrels position in the capsid shells in a variety of orientations with the insertions between β-strands having a great range of sizes, giving each virus the ability to evolve a distinct structure, function, and antigenic identity. Indeed, the structure of nudaurelia capensis omega virus (NωV), an insect tetravirus, revealed an entire 133-residue immunoglobin-like domain inserted between strands E and F that forms a major portion of the particle surface. Just as prevalent, the very N- and C-termini of the capsid proteins are often extended polypeptides that do not form part of the barrel. Those portions of the extended termini close to the barrel can have ordered structure to various degrees depending on the local (quasi-)symmetry environment (see **Figure 1**), and tend to engage in varied types of interactions, such as binding one or more nearby subunits and/or nucleic acid, that play critical roles in particle assembly, stability, and nucleic acid packaging.

Other Folds

While the β-barrel remains a common element in a wide range of virus structures, other capsid subunit folds have been discovered in both enveloped (not shown) and nonenveloped particles (**Figure 2**). The nonenveloped subunits also form icosahedral shells as well as helical rods. The structure determination of the $T = 3$, ssRNA bacteriophage MS2 in 1990 revealed the first new fold for an icosahedral virus capsid subunit. It consists of a five-stranded β-sheet that faces the inside of the particle, with a hairpin loop and two helices facing the exterior. The only structural similarity to the particles formed by β-barrels was their assembly into a $T = 3$ quasi-icosahedral shell. Just 10 years later, the head (capsid) structure of the $T = 7$, dsDNA tailed bacteriophage HK97 showed another new capsid subunit fold, and the same fold has also been found in bacteriophage T4 capsids. Other than the high probability that a capsid subunit with a β-barrel is going to form an icosahedral particle, no other general themes can be derived from the variety of subunit folds to predict particle size, quasi-symmetry, or host specificity.

Completely Symmetric Capsids

$T = 1$ Icosahedral Particles

The simplest of the spherical particles, the $T = 1$ capsids, have only one protein subunit in each of the 60 positions related by icosahedral symmetry. This has been the symmetry found in three of the four known encapsulated satellite viruses, one of which is the 180 Å diameter,

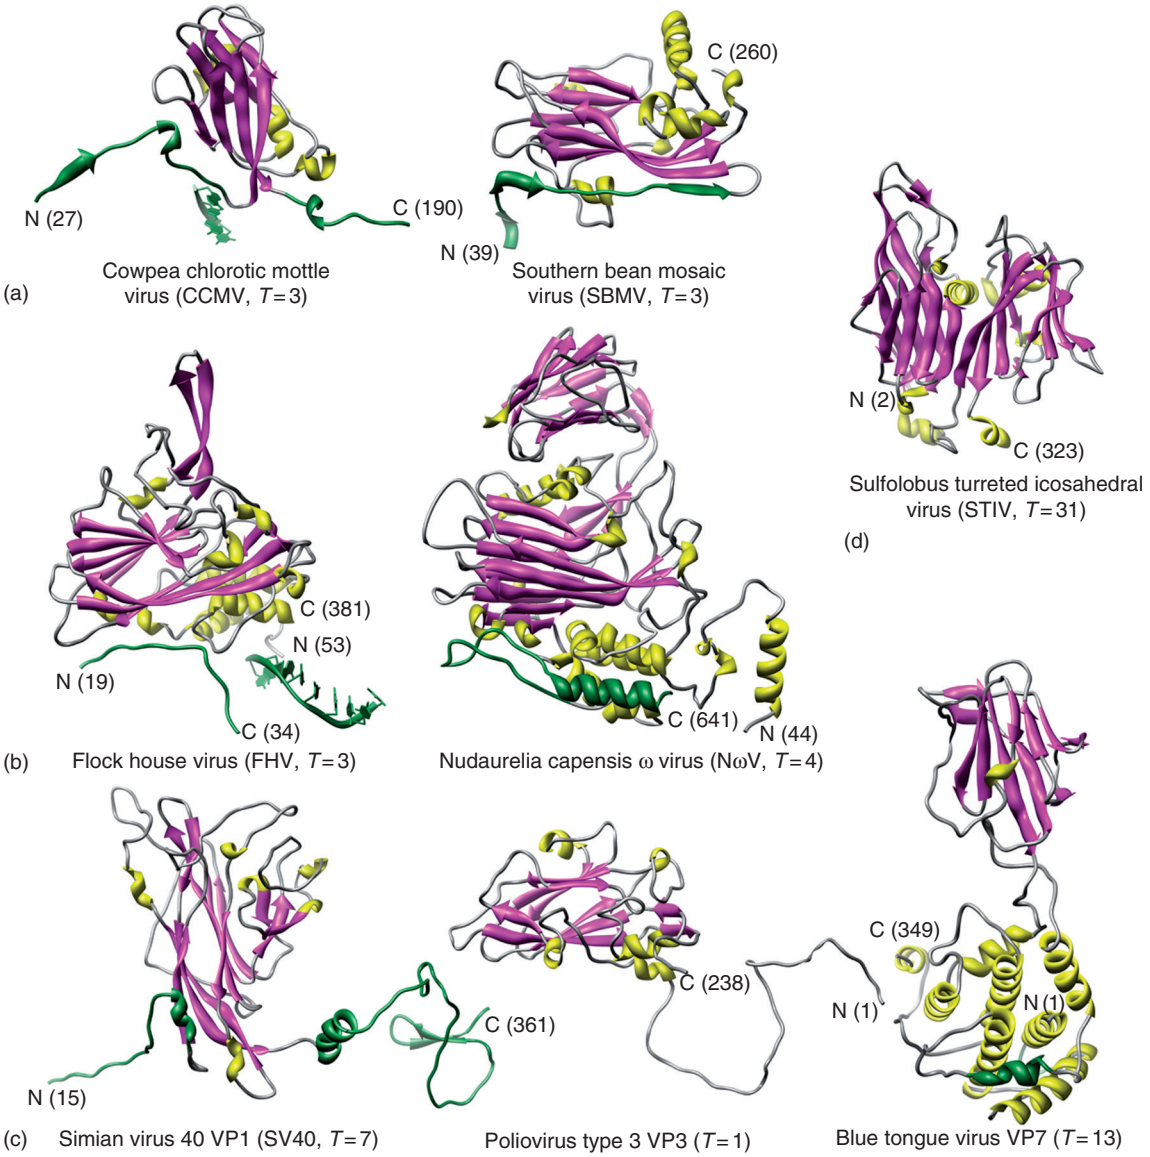

Figure 1 Structure of (a) plant, (b) insect, (c) vertebrate, and (d) archaea virus protein subunits that assemble into icosahedral shells. The name of the virus appears below the corresponding protein subunit along with the capsid triangulation number. The N- and C-termini are labeled with the residue numbers in brackets. The N-termini (and sometimes the C-termini) usually consist of highly charged residues associated with the interior of the virus particle and/or the packaged nucleic acid. As such, they do not follow icosahedral symmetry and are regularly disordered (invisible) in the final structures. Many virus subunit structures determined to near atomic resolution have the β-barrel fold and/or insertions with nearly all β-structure (colored magenta). Multiple copies (from 180 to 900) of the single subunit shown for each virus, except for that of poliovirus, form the entire icosahedral protein shell. Assembly of icosahedral virus particles with more than 60 subunits requires quasi-symmetric interactions often involving subtle to extensive differences in structure at the subunit N- and C-termini. The subunit regions involved in quasi-symmetric interactions critical to virion structure and assembly are colored green (only a single variation is shown for each virus; not yet known for STIV). The 'switch' in structure between identical subunits is a response to differences in the local chemical environment, defined by the number of subunits forming the icosahedral shell, in order to maintain similar bonding between neighboring subunits. The structural variations include the presence or absence of highly ordered RNA structure (green stick models) in FHV and CCMV. Poliovirus utilizes multiple copies of two additional subunits highly similar to VP3 to form a complete virion. Thus, there is no quasi-symmetry in poliovirus (note the absence of any green highlights) since neighboring subunits are different proteins.

ssRNA satellite tobacco mosaic virus (STMV) particle (**Figures 3(a)** and **3(b)**). The small, compact STMV capsid subunits (159 a.a.) have the β-barrel fold with the β-strands running roughly tangential to the particle curvature with the B–C, D–E, F–G, and H–I turns pointing toward the fivefold axes. This is a common subunit orientation and will be simply called 'tangential' going forward. The turns between strands are all short (no insertions),

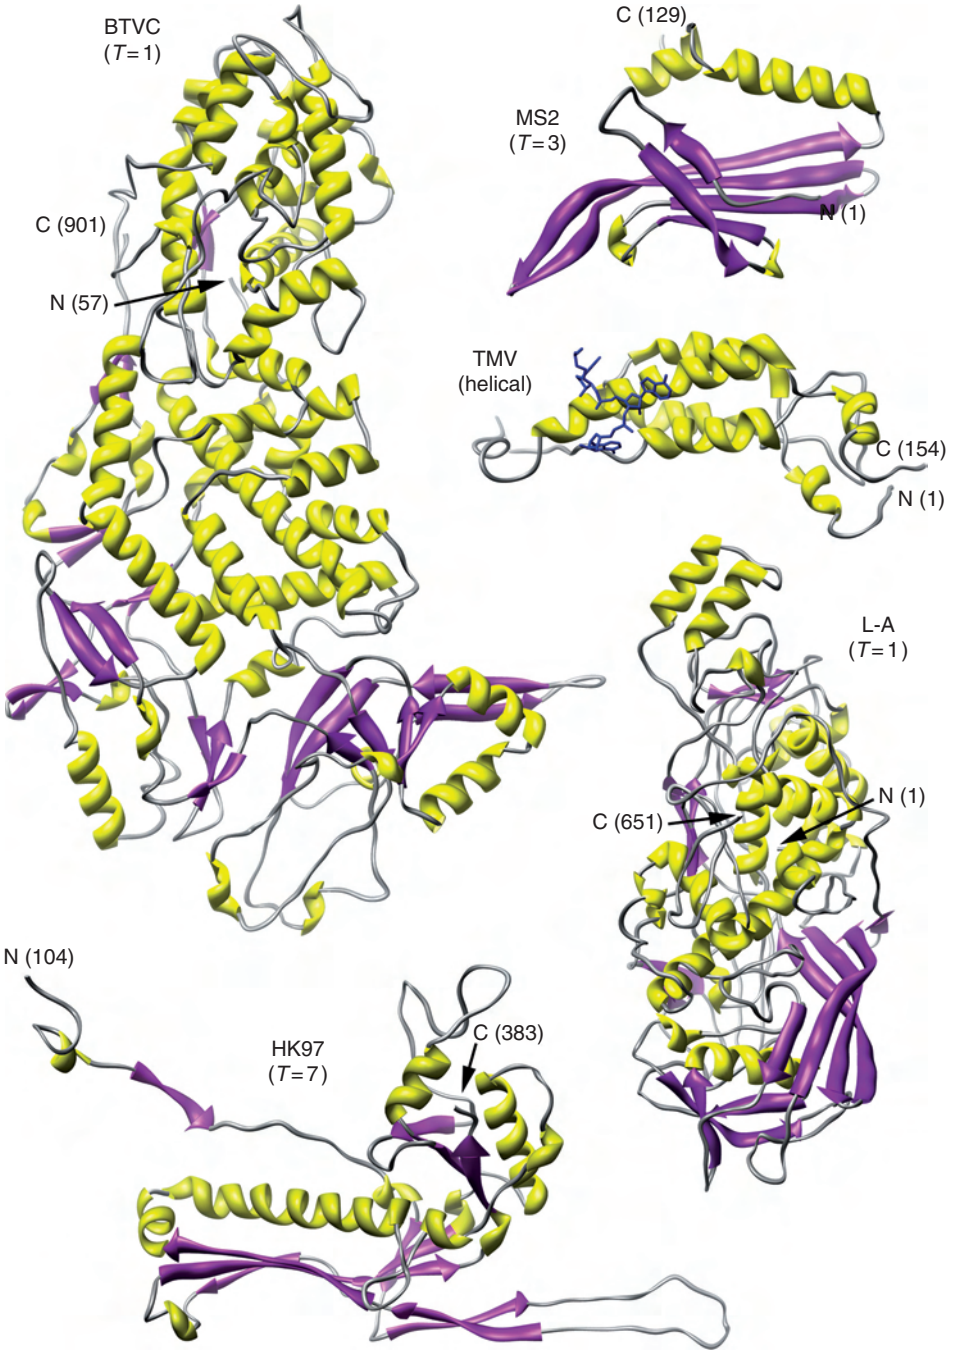

Figure 2 Structure of capsid subunits with folds other than the β-barrel. The name of the virus appears next to the corresponding protein subunit along with the capsid triangulation number (if applicable). The N- and C-termini are labeled with the residue numbers in brackets. With the exception of MS2, helical structure is dominant, with some β-sheet formations mixed into the folds. The subunit of the helical TMV rod is mostly composed of a four antiparallel α-helix bundle that forms the core of the rods, but has a small β-sheet away from the axis that forms the rod surface. The three bound nucleotides per TMV subunit are shown as a blue stick model (see the section titled 'Helical particles'). Both the BTVC (inner shell) and L–A subunits form $T = 1$ particles with two copies of the subunit in the icosahedral asymmetric unit (discussed in text), but do not share any detectable structural homology. The BTVC inner shell subunit is the largest capsid subunit determined to near-atomic resolution.

with only an extended N-terminus jutting 60 Å from the barrel that helps form both the threefold and twofold symmetry related interactions (trimers and dimers) via hydrogen bonds and extension of antiparallel β-sheets. The strongest inter-subunit contacts occur at the capsid subunit dimers, where a large number of both hydrophobic and hydrophilic interactions form across a large buried surface between the subunits. The interior surface of the

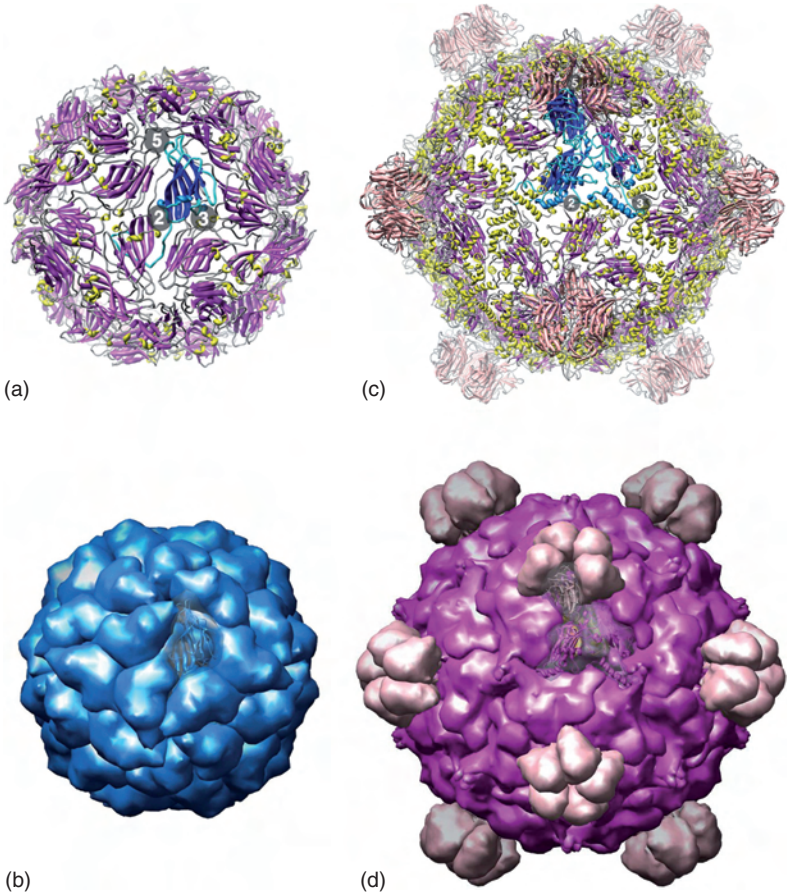

Figure 3 Structures of two $T=1$ particles viewed down an icosahedral twofold rotation axis (approximately to scale). STMV is displayed in (a) and (b), and ΦX174 in (c) and (d). The top images show all 60 capsid subunits rendered as ribbon drawings (β-strands – magenta or pink; helices – yellow), with the icosahedral asymmetric unit (IAU) shown all in blue. The fivefold, threefold, and twofold icosahedral axes are labeled with semitransparent gray circles containing the appropriate rotation number in white. The images are depth-queued such that features further away fade into the white background. The back of the particles are purposely faded (invisible) to make a clearer representation. The bottom images are surface representations of the same structures above, with the IAU shown as a transparent surface to show the ribbon drawing of the capsid subunits. Note the more compact look of STMV due to the close approach of complementary surfaces on the β-barrels vs. the more spread-out look of ΦX174 due to its use of extended loops to create a contiguous capsid. The exterior of the ΦX174 shell includes the G-protein (pink subunits), which surrounds hydrophilic channels at the fivefold axes, and has a β-barrel fold that is oriented nearly parallel to the fivefold axes such that they form 12 broad spikes on the particle surface. This will be called the 'axial' orientation. This increases the particle dimensions at these axes by 60 Å but does not contribute to the enclosed volume as they sit atop an essentially complete protein shell. (b, d) Courtesy of the Viperdb web site.

STMV capsid dimers binds a large section of ordered double-helical RNA. Two additional symmetry-related subunits interact with the RNA via their extended N-termini. The protein–RNA interactions are split between direct side-chain bonds to the ribose sugars, and water-mediated hydrogen bonds by residues of both the local subunit dimer β-barrels and N-termini. Altogether the ordered RNA accounts for about 59% of the packaged nucleic acid. Although STMV is one of the simplest icosahedral viruses, its features demonstrate many of the basic protein–protein and protein–RNA bonding schemes that have been observed in larger and more complex particles.

While an advantage of the $T=1$ capsid is its equivalent subunit environments, its major limitation is the small particle volume. To create larger shells, the subunits either have to be larger or there have to be more of them. The former is seen in the crystal structure of the ssDNA bacteriophage ΦX174 capsid (**Figures 3(c)** and **3(d)**). Its 426 a.a. F proteins form a 340 Å diameter $T=1$ icosahedral particle, which has nearly fourfold greater volume compared to the satellite virus capsids. Each subunit has the β-barrel fold, but it accounts for only one-third of the F protein. The remainder of the capsid subunit is composed of long loops inserted between the β-strands that make up the majority of inter-subunit interactions and capsid surface. ΦX174 has additional capsid proteins, but the contiguous protein shell is made up of only the F protein. While a larger subunit can create a viable amount of enclosed volume, native $T=1$ particles are uncommon. This may be due to

inefficiencies in dealing with the larger amount of genome dedicated to the major capsid protein and the more complex structural requirements of a single large subunit to build a stable and functional particle.

Helical Particles

The only high-resolution structures of helical viruses are from three members of the genus *Tobamovirus*, whose type member is TMV. The tobamoviruses form rod-shaped particles 3000 Å long and 180 Å in diameter, with a central hole about 40 Å across. The particles are built from over 2100 identical capsid protein subunits that are 158 a.a. in size, and arranged in a right-handed helix with 49 subunits in every three turns and a pitch of 23 Å. The subunit has a narrow, elongated structure composed of a four-helix bundle on one end, and a small β-sheet on the other (**Figure 2**). The subunits sit perpendicular to the particle axis, with the helix end of the subunit nearest the center and the β-sheet end forming the outer surface of the rod. Neighboring subunits stack upon one another in the particle helix such that two helices of each protein interact with two others from the neighboring subunit, forming another four-helix bundle to build the rod.

The structure of the TMV particle determined in the late 1980s revealed the first details of virus capsid protein interactions with nucleic acid. A long loop inserted between two of the subunit helices forms the interior channel of the particle that includes a continuous RNA binding site at the edge of the helices. The entire RNA genome is well ordered in the TMV structure by conforming to the helical symmetry of the coat protein stacking. There are three nucleotides bound to each protein subunit (**Figure 2**) over the entire length of the rod, which adds subunits during assembly until the entire genome is encapsidated. The RNA is bound at its phosphate groups by direct, calcium-mediated, and probably water-mediated interactions with nearby arginine and aspartic acid residues, and at its sugars and bases by hydrophobic complementary, polar interactions, and a few hydrogen bonds from local arginine and aspartic acid residues. This mode of nucleic acid binding showed that, since the viral genome sequences do not share the symmetry of their enclosing particles, interactions with the coat protein are complementary to the nucleic acid, but non-base-specific to ensure that the entire genome is encapsidated. The same general principles continue to be found in the ordered protein–nucleic acid interactions observed in icosahedral particle structures.

Quasi-Symmetric Capsids

T = 3 Icosahedral Particles

Icosahedral particles built from multiples of 60 identical capsid subunits exist in great numbers, and are arranged with many variations on the quasi-symmetry first predicted by Caspar and Klug in 1962. In one of the closest matches to their predictions, 90 coat protein dimers (180 total coat proteins) of the ssRNA plant cowpea chlorotic mottle virus (CCMV) assemble with nearly ideal $T = 3$ quasi-symmetry into the shape of a 280 Å diameter truncated icosahedron, which is defined by planar pentamer (formed by A subunits) and hexamer (formed by B and C subunits) morphological units (capsomers) at the fivefold and threefold (quasi-sixfold) axes, respectively (**Figure 4**, top). The 190 a.a. capsid subunit folds into a small β-barrel with short loops between strands, but has both extended N- and C-termini (**Figure 4**, bottom left). All 180 subunits have the axial orientation with the N-termini extending toward the center of the pentamers and hexamers, and the C-termini extending outward into neighboring capsomers by reaching across the twofold axes. The very ends of the C-termini are clamped in between the β-barrel and N-terminal extension of the twofold related subunit, forming the largest number of interactions between capsid subunits and tying the capsomers together. This occurs at both the twofold and quasi-twofold axes with high fidelity. The dimer interactions also define the dihedral angles between the planar capsomers; the angles between hexamer–hexamer (twofold) and pentamer–hexamer (quasi-twofold) interfaces only differ by 4° (**Figure 4**, bottom right), producing a smooth particle curvature. A triangular unit of A, B, and C subunits defines the icosahedral asymmetric unit (IAU), and also a high-fidelity quasi-threefold axis. Calcium and RNA binding sites are preserved at all three interfaces (calcium site exterior, RNA site interior, and under the calcium site) with nearly equivalent positions of the coordinating side chains.

The pentamer and hexamer units show more differentiation. Besides subtle contact changes between the β-barrels, the N-termini of the hexamer subunits form a nearly prefect sixfold symmetric parallel β-tube about the threefold axes in an impressive display of quasi-sixfold interactions. The N-termini of the pentamer subunits extend a bit toward the fivefold axes but form no structure due to disorder after residue 42. Interestingly, deletion of the β-hexamer in one study did not prevent hexamers from forming, but did destabilize the particle. Other than the differences seen at the capsomer centers, the remainder of the interactions between the A, B, and C subunits are subtly changed to accommodate the differences in chemical environments, rather than switched from one form to another, and may explain the highly pleomorphic properties of the CCMV capsid subunit.

T = 4 Icosahedral Particles

The ssRNA insect tetraviruses remain the only known viruses that have a nonenveloped, $T = 4$ capsid. The crystal structure of the 400 Å diameter NωV capsid in

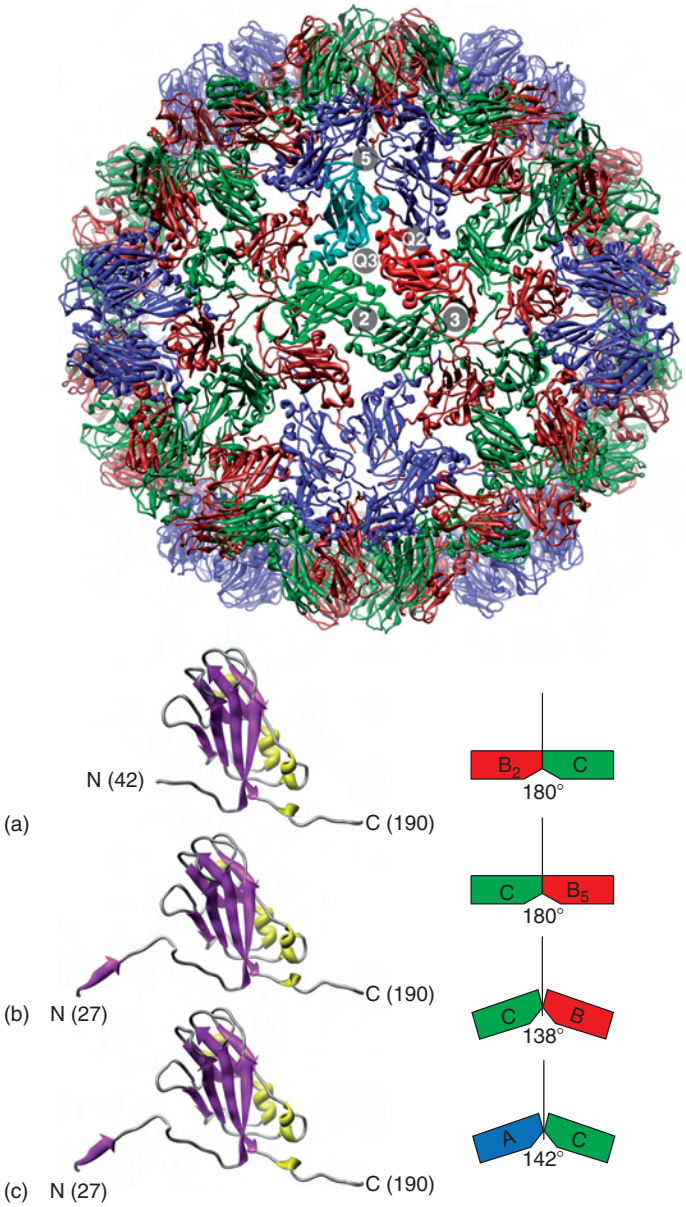

Figure 4 Structure of the $T = 3$ CCMV particle viewed down an icosahedral twofold axis. Icosahedral and quasi-symmetry (Q) axes are labeled as in **Figure 3**. The quasi-sixfold axes are not labeled as they coincide with the icosahedral threefold axes. (top) The entire CCMV particle with A-subunits colored blue, B colored red, and C colored green. An IAU is shown above the twofold axis in brighter colors and larger ribbons. The calcium sites between quasi-threefold related subunits are strongly implicated in CCMV particle expansion, which occurs in the absence of divalent metal ions at high pH. The CCMV crystal structure shows that under these conditions the charged residues of the calcium-binding site would cause a repulsion between quasi-threefold related subunits, and a cryo-EM structure of the swollen form of CCMV confirmed the opening of large holes at the quasi-threefolds. Indeed, swollen CCMV breaks apart into subunit dimers and RNA in high salt concentrations, and under various solution conditions, can reassemble into a number of structures including $T = 1$, $T = 3$, and $T = 7$ particles, long tubes, multi-shelled particles and tubes, and laminar plates. It is one of the most pleomorphic viral subunits ever studied, but amazingly only makes $T = 3$ particles in plant infections. (Bottom left) Individual structures of the proteins in the A, B, and C subunit environments colored as in **Figure 2**. Note they are closely identical except for the lack of extended N-terminal structure in A, and slightly varying directions taken by the C-termini away from the β-barrels (not readily visible in these views). (Bottom right) Diagrammatic representation of the flat and bent subunit/capsomer interfaces. Individual blocks represent the subunits as viewed tangentially to the particle curvature. Colors and letters designate the subunit type with the dihedral angle between them given underneath.

1996 showed the 644 a.a. capsid subunit has three domains: an exterior Ig-like fold, a central β-barrel in tangential orientation, and an interior helix bundle (**Figure 5**, right side). The helix bundle is created by the N- and C-termini of the polypeptide before and after the β-barrel fold, and the Ig-like domain is an insert between the E and F β-strands. All 240 of the NωV capsid subunits undergo autoproteolysis at residue 571 after assembly,

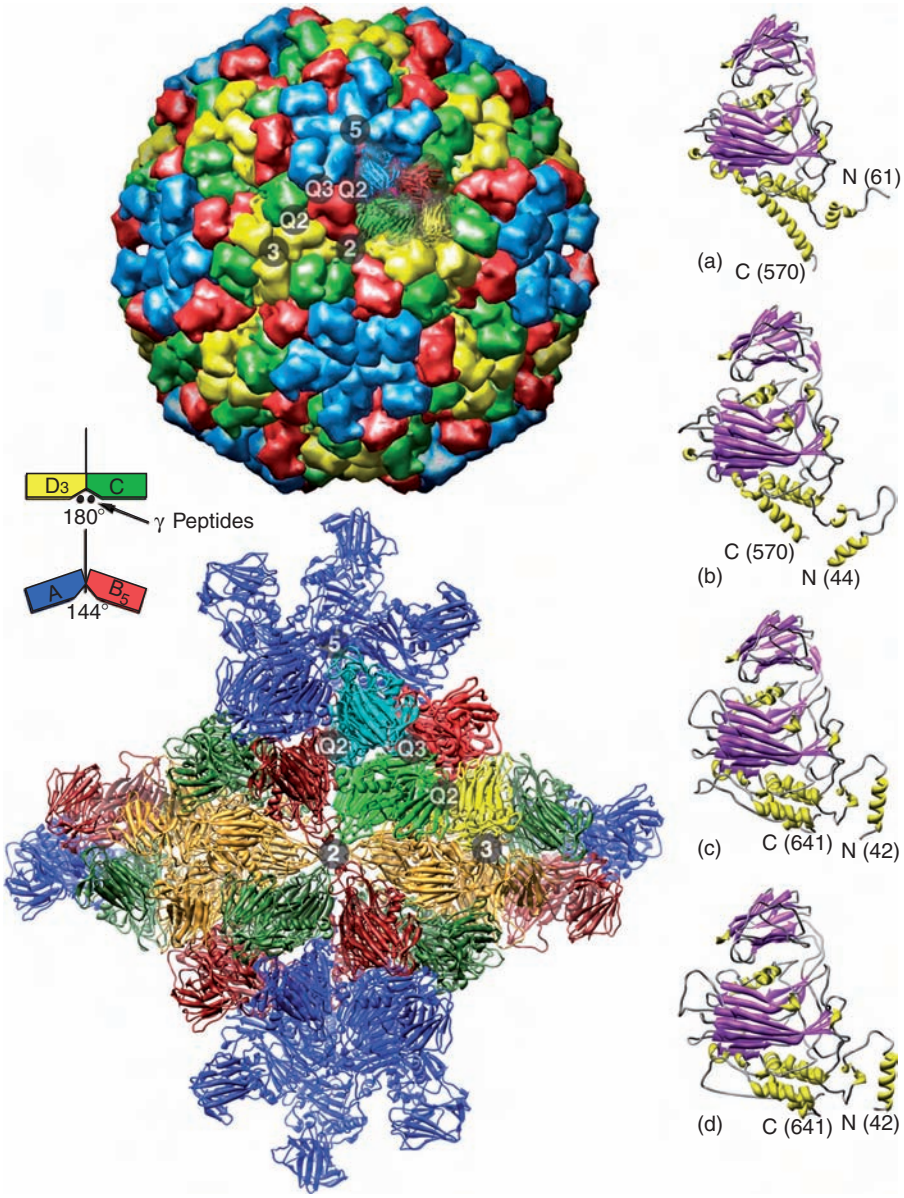

Figure 5 Structure of the $T = 4$ NωV particle viewed down an icosahedral twofold axis. Icosahedral and quasi-symmetry (Q) axes are labeled as in **Figure 3**. The low-fidelity quasi-sixfold axes are not labeled as they coincide with the icosahedral twofold axes. (Right) Individual structures of the proteins in the A, B, C, and D subunit environments colored as in **Figure 2**. While the basic folds and domains are similar, they differ considerably at both the N- and C-termini, in loop structure at one end of the barrel, and slightly in position and orientation of the Ig domains. In particular, the C- and D-subunits have additional ordered polypeptide in the helical domain that dictates switching between bent and flat contacts in the capsid architecture (see below and text). (Left) Surface representation of the entire $T = 4$ particle (as in **Figure 1**) and a more detailed ribbon representation of the area between the four fivefold axes surrounding the center twofold axis. A diagrammatic representation of the subunit/capsomer interfaces is also shown as in **Figure 3**. Complete pentamers are only shown on the top and bottom of the ribbon image. The A-, B-, and C-subunits are colored as in **Figure 3**, and the D-subunits are colored yellow. An asymmetric unit is shown above and to the right of the twofold axis in brighter colors and larger ribbons (also shown in surface representation above as ribbons). The $T = 4$ arrangement can be thought of as two sets of triangles: one set is formed by the quasi-threefold related A-, B-, and C-subunits, and the other is formed by the icoshedral threefold related D-subunits. The dihedral angles of the interfaces between two ABC units (144°), and between ABC and DDD units (180°; both are quasi-twofold related contacts) creates flat triangles with fivefold axes at the corners, and bending between them along the lines from fivefold to twofold axes. Surface image courtesy of the Viperdb web site.

leaving the cleaved portion of the C-terminus, called the γ-peptide, associated with the capsid. The fold and tangential orientation of the β-barrel together with the autoproteolysis revealed a strong relationship between tetraviruses and the $T = 3$ insect nodaviruses. Indeed, the folds and catalytic sites superimpose with little variation, and a γ-peptide also exists in the nodaviruses. Unlike in CCMV, the quasi-symmetry of these insect particles is

obviously controlled by a molecular switch (**Figure 5**, left side). In NωV, a segment of the γ-peptide (residues 608–641) is only ordered in the C and D subunits, and functions as a wedge between the ABC and DDD units to prevent curvature and create a flat contact. The interface between two ABC units is bent partly due to the lack of ordered γ-peptide. A similar situation exists in the nodaviruses, except that the ordered polypeptide between twofold related C-subunits in the $T=3$ particle comes from the A-subunit N-terminus, and ordered duplex RNA also fills the interface. The structural information from the tetravirus group has defined important relationships and some common themes in the biology of the insect viruses.

T = 7 Icosahedral Particles

All three $T=7$ capsid structures determined at near atomic resolution are dsDNA viruses with unique features: two mammalian polyomaviruses, SV40 and polyoma virus, and the head of the λ-like tailed bacteriophage HK97 from the family *Siphoviridae*. The 500 Å diameter SV40 capsid is constructed of 72 pentamers arranged with $T=7d$ quasi-symmetry, not 12 pentamers and 60 hexamers as predicted by quasi-equivalence theory. Thus, 60 of the SV40 pentamers are actually in hexavalent environments as they are located in positions that are occupied by hexamers in an ideal $T=7$ lattice. As the valency of a true $T=7$ lattice is present, it was a surprise to discover it could be achieved without the expected number of identical subunits or domains (i.e., five subunits instead of six). The pentamers contain five copies of the 364 a.a. VP1 protein, which have the axial β-barrel orientation and extended C-terminal arms. Interlocking secondary structures of the G-strands and DE loops with clockwise neighbors form the intimately associated pentamers. The C-arms of all five subunits in each pentamer reach outward to one of three specific types of neighboring pentamers depending on the local environment (threefold and two types of twofold clusters), and form another β-strand between the N-terminus and BIDG sheet of the neighboring subunit (a similar clamp to that of CCMV). This ties the neighboring pentamers together in a general way determined by the position and valency of each pentamer. Remarkably, the VP1 proteins and clamp structures in the pentamer cores are structurally identical, and only the direction and ordered structure of the C-terminal arms are changing as they switch contacts between the nonequivalent pentamers.

By comparison, the 650 Å diameter HK97 capsid is a true $T=7l$ icosahedron, composed of 420 subunits arranged in 12 concave pentamers and 60 planar hexamers. Strikingly, the 385 a.a. protein subunit has a new virus fold (**Figure 6**). Each subunit forms two covalent isopeptide bonds (cross-links) with neighboring subunits on opposite sides of the protein to create topologically linked protein rings arranged with icosahedral symmetry, also a new find in protein structure studies. Notably, the cross-links are formed between subunits that encircle the pentamers and hexamers (one from each neighboring capsomer), not between the subunits forming them. This defines how their complex interweaving occurs at the particle threefold and quasi-threefold axes (**Figure 6**). The fact that this is the final mature state of the HK97 head particle, and that the cross-links are not yet formed in particles at the early to mid-stages of the capsid maturation process, has led to informative studies on capsid dynamics using HK97 as a model system. The final step of HK97 maturation involves formation of the final 60 cross-links in the transition from expansion intermediate IV (EI-IV) to the mature capsid (head II). The pentons appear to be dynamic, oscillating up and down relative to the contiguous capsid shell, until cross-linked. See the article 'Principles of Virus Structure' for animations of the entire transition from the prohead state through head II.

T = 13 Icosahedral Particles

The 700 Å diameter dsRNA blue tongue virus core (BTVC) particle remains the largest molecular structure ever determined by X-ray crystallography to near-atomic resolution. The core particle has two shells: an inner $T=1$ particle, composed of 120 large (901 a.a.) VP3 proteins (two in each icosahedral asymmetric unit), which packages a few RNA polymerases and 10 strands of dsRNA, and an outer $T=13l$ particle composed of 780 VP7 proteins (349 a.a.), for a total of 900 capsid proteins and a molecular weight of over 54 000 000 Da. The VP7 subunits form a trimer in solution. The trimer structure was determined by X-ray crystallography and combined with cryo-EM images of BTVC to determine the entire BTVC crystal structure. The VP7 subunit has two domains, an outer β-barrel and an inner helix bundle (**Figure 1**), both of which have extensive contacts in the trimer. In an interesting twist, the β-barrel is actually an insert between two helices in the linear VP7 sequence, and the helix bundle is responsible for the majority of interactions between trimers in the assembled shell. The VP7 trimers are postulated to 'crystallize' or assemble on the inner shell's surface into the 12 pentamers and 120 hexamers, which follow quasi-symmetry with high fidelity having very little differences in their intercapsomer interactions. In contrast, the inner $T=1$ shell breaks from quasi-equivalence theory by using large-scale flexing of the two huge VP3 proteins to generate similar shapes of interactions in the absence of similar contacts, and build a nearly featureless hydrophobic surface for interaction with VP7. Together, these shells present a dazzling array

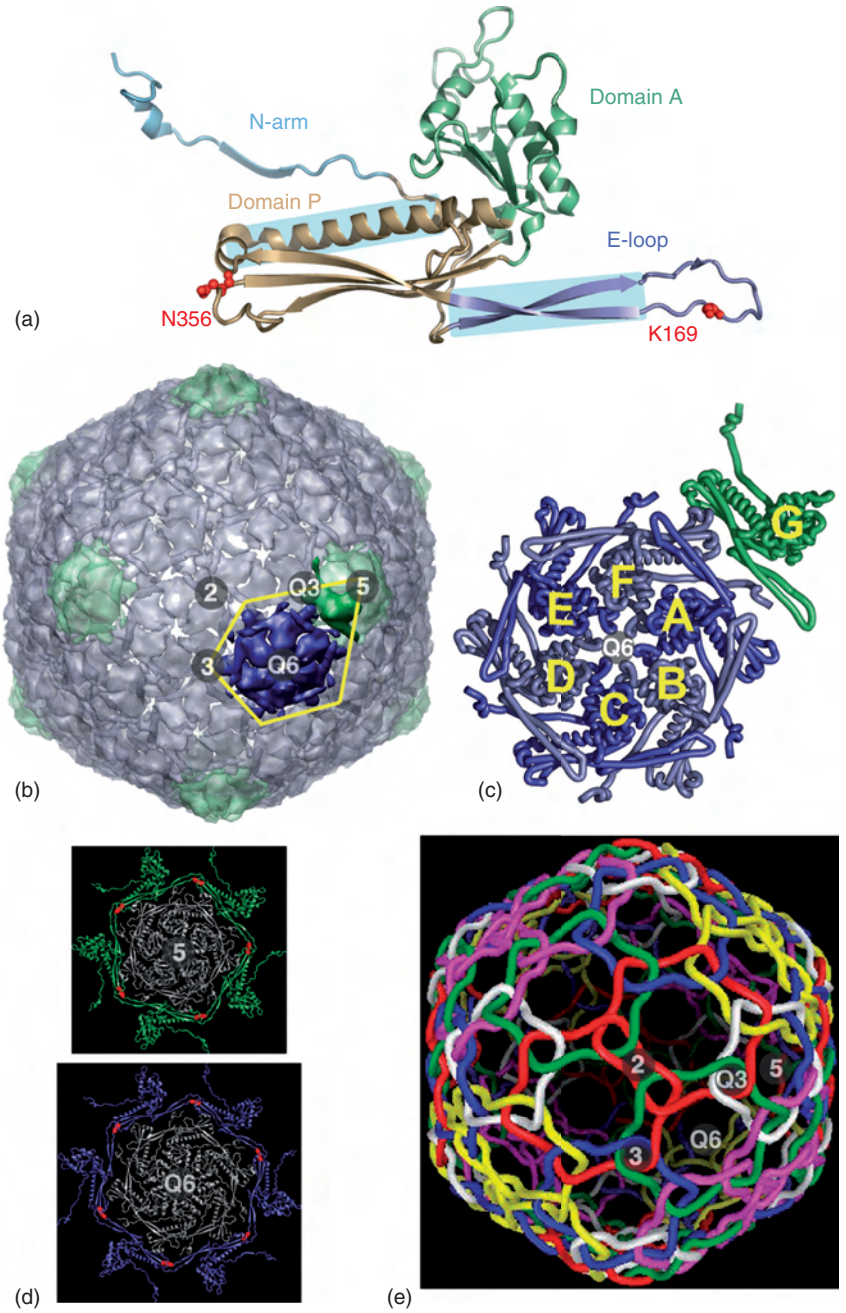

Figure 6 Structure of the $T = 7$ HK97 particle. Icosahedral and quasi-symmetry (Q) axes are labeled as in **Figure 3**. (a) HK97 subunit fold. The small HK97 subunits have mixed α/β structure, forming two domains in the shape of an L that have a continuous hydrophobic core, and placing the two residues involved in cross-linking other subunits (red) on opposite sides of the protein. (b) Surface representation of the entire HK97 capsid viewed down an icosahedral twofold axis, with pentamers colored separately from hexamers. The IAU is outlined in yellow. Unlike the $T = 3$ and $T = 4$ structures, none of the hexamers sit on icosahedral axes. (c) Ribbon diagram of the seven subunits in the IAU showing how they align such that the P-domains and E-loops overlap to define the sides of the local capsomers, but place their tips (with the cross-linking residues) outside the capsomer to be accessible to neighboring subunits. (d) The two types of cross-linked subunit 'circles' or 'rings' in HK97. The surrounding cross-linked subunits (one from each neighboring capsomer) are shown in green (5-circle) or blue (Q6-circle), with the cross-link shown in red. (e) Diagrammatic representation of the interlocking cross-links in HK97. The 5- or Q6-circles, now with subunit and cross-links just represented by tubes, are colored separately showing how they form molecular chainmail by interweaving at the icosahedral and quasi-threefold axes. This molecular chainmail stabilizes the unusually thin 18-Å-wide protein shell (only half the width usually formed by capsids composed of β-barrel subunits), which can be described as a protein balloon. The capsids are also stabilized by other extensive inter-subunit interactions with up to nine other coat proteins. The N-arm, which is not involved in the cross-links, extends 67 Å away from the subunit to contact subunits in neighboring capsomers. (a–d) Courtesy of Dr. Lu Gan. (e) Courtesy of Gabe Lander.

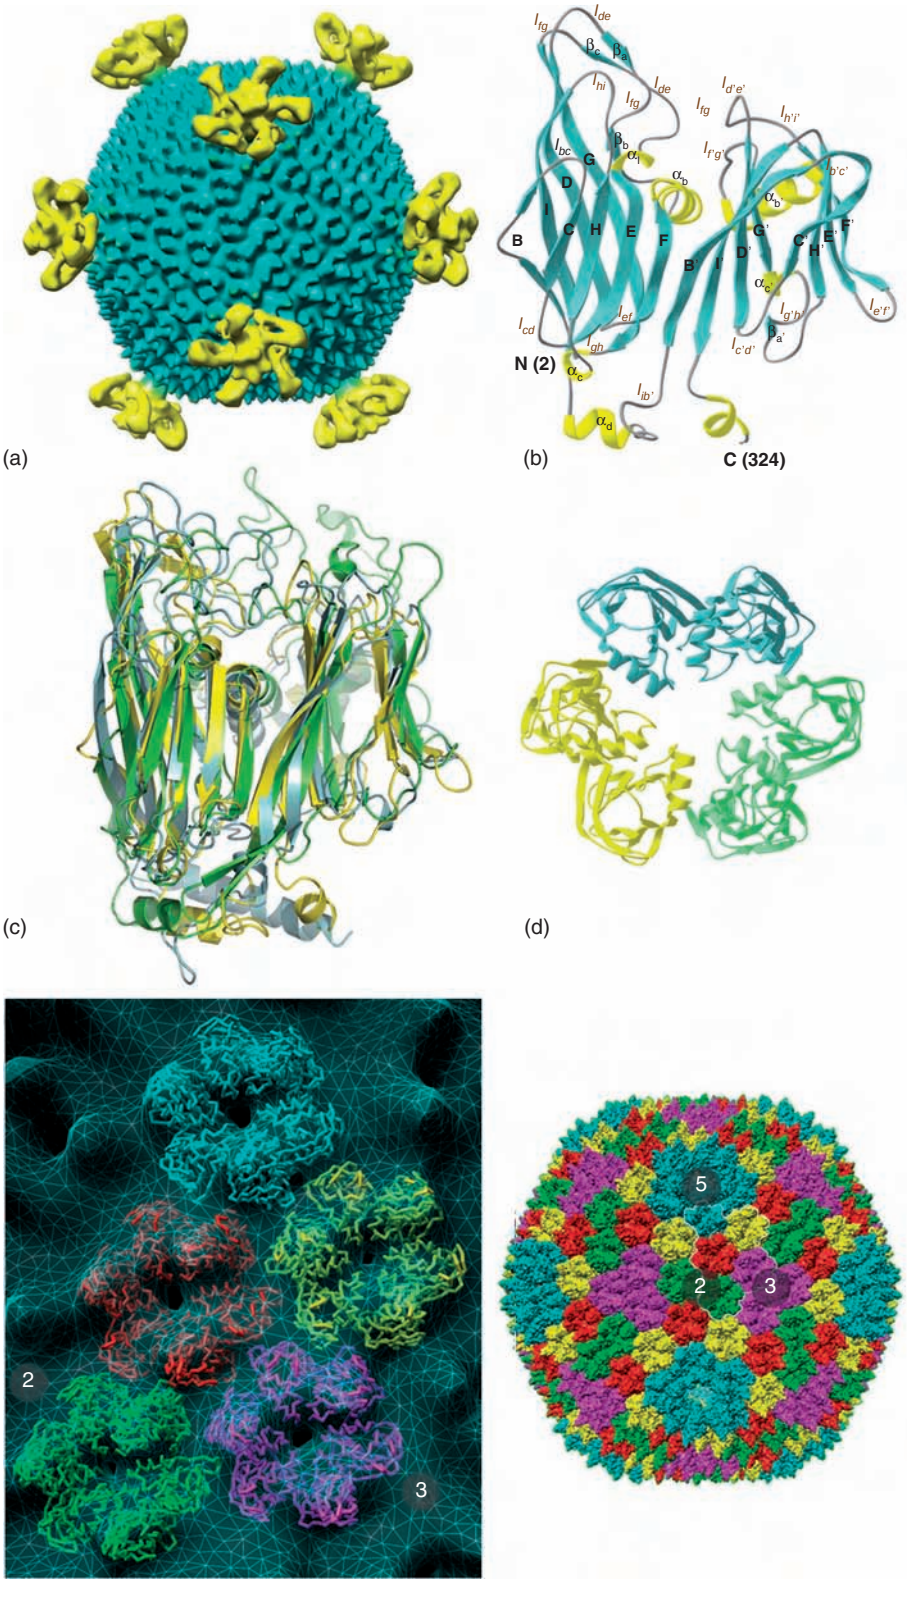

Figure 7 Continued

of protein interactions that go from near perfect conformity with quasi-equivalent theory to defining a new category of viral subunit interactions in the $T=1$ particle.

T = 25 and Larger Icosahedral Particles: The Double-Barrel Subunit

Virus capsids having to assemble with $T=25$ quasi-symmetry or higher have avoided the enormous challenge of accurately placing 1500 or more individual proteins in a shell by reducing the problem to just a few related hexon locations. The crystal structure of the hexon from the dsDNA, $T=25$ adenovirus capsid revealed it is a trimer of three identical 967 a.a. proteins. Each protein has two axially oriented β-barrel domains. In the trimer, the barrels are almost precisely related by a pseudo-sixfold axis such that each forms a corner of the hexon base. The hexon is the building block for the particle and is extremely stable due to interpenetrating polypeptides in the trimer. Thus, a stable trimer satisfies the hexavalent lattice positions in $T=25$ adenovirus as the stable pentamers do in $T=7$ SV40. Combined with cryo-EM images of the capsid, these structures revealed that there are only four different hexon-binding sites in adenovirus (pentons have a different subunit), and that much larger hexon facets can be constructed in this manner. In a recent series of groundbreaking discoveries that surprised virus researchers, a combination of both cryo-EM and crystallography methods revealed that the hexon structures of large dsDNA viruses in all domains of life have similar 'double-barrel trimers' forming pseudo-hexagonal shapes. These include adenovirus (eukarya), $T=25$ PRD1 (bacteria), $T=169$ paramecium bursaria chlorella 1 virus (PBCV-1, green algae), and, most recently, $T=31$ sulfolobus turreted icosahedral virus (STIV, archaea) (**Figure 7**). When the double-barrel subunits from all four viruses are superimposed, over 46% of their polypeptides are within 2.2 Å r.m.s.d. of each other. For the first time, these apparently complicated and unrelated viruses infecting quite different hosts have been solidly linked by their structures, supporting the hypothesis that at least one virus lineage originated before life separated into three domains.

Bacilliform Particles

The ssRNA plant alfalfa mosaic virus (AMV), a member of the family *Bromoviridae* that includes CCMV, forms four types of bacilliform particles composed of one of the four genomic RNAs and a single 220 a.a. capsid subunit. The particles are 180 Å in diameter and range in length from 300 to 570 Å. The spherical ends have $T=1$ symmetry, while the cylindrical bodies have a repeating sixfold symmetry with large holes at the hexamer centers. After a mild trypsin treatment and removal of RNA, the capsid subunit readily forms $T=1$ particles that crystallize and their structure has been determined. The $T=1$ particle is 220 Å in diameter with large holes 35 Å across at the fivefold axes. The subunit is a simple β-barrel in the axial orientation with extended termini at the base. The C-termini reach across the twofold axes to hook between the N-terminus and β-barrel of the symmetry-related subunit in a strikingly similar fashion to the structure of the CCMV particle. Thus, this structure of the AMV endcaps helps demonstrate how the highly pleomorphic capsid proteins of bromoviruses can assemble into several particle forms via strong but flexible dimer contacts depending on solution conditions.

Psuedo-Symmetric Capsids

P = 3 Icosahedral Particles

Instead of having three copies of a single protein in slightly different chemical environments, a number of viruses have evolved with two or three different proteins in each environment that have unique primary structures but similar folds. The coat protein arrangements are similar to that proposed for $T=3$ lattices such that they are given the $P=3$ (pseudo $T=3$) designation. Unlike the single protein in T capsid arrangements, the different

Figure 7 Structure of the $T=31$ STIV capsid and major coat protein (MCP). (a) The cryo-EM image reconstruction of the entire STIV capsid viewed down an icosahedral twofold axis. The shell formed by 900 copies (300 trimers) of the MCP is shown in blue, and the 200 Å tall turrets that compose the fivefold axes are shown in yellow. (b) Crystal structure of the MCP, with β-strands colored cyan and helices yellow. Like other large dsDNA viruses, the protein folds into two covalently linked β-barrels, one shown on the left and the other on the right. Interestingly, the large capsid subunit of the plant comoviruses is the only one outside the large dsDNA virus families with the double-barrel fold. (c) Superposition of the major coat proteins from STIV (yellow), PRD1 (cyan), and PBCV-1 (green) in approximately the same orientation as (b), showing the closely similar double-barrel folds. (d) Model of the STIV MCP trimer, based on that seen in the other dsDNA viruses. Each protein is colored separately, and each barrel makes the corner of one of the five unique hexon units seen in the assembled $T=31$ virus. (e) Top view of the STIV asymmetric unit from the cryo-EM structure (shown as a blue lattice) with Cα traces of the MCP trimer fitted in the hexon positions. Icosahedral axes are labeled as in previous figures, with the blue hexon just below the fivefold axis. The highly correlated fit between the atomic model and cryo-EM reconstruction reveals possible inter-subunit interactions, quasi-symmetry, and how the main protein shell is constructed, shown in (f). (f) Pseudo-atomic model of the complete MCP shell using the same color scheme as in (e), with the asymmetric unit outlined in white. Note the modularity of the hexons, which theoretically can be exploited to form capsids of extremely large size such as the 5000 Å diameter mimivirus. Courtesy of Dr. Reza Khayat *et al*., as published in Khayat R, Tang L, Larson ET, *et al*. (2005) Structure of an archaeal virus capsid protein reveals a common ancestry to eukaryotic and bacterial viruses. *Proceedings of the National Academy of Sciences, USA* 102: 18944–18949.

capsid proteins in P arrangements are free to mutate, function, and form interactions independent of one another but more of the genome must be used to encode multiple capsid proteins. Two well-studied families with $P = 3$ capsids are the ssRNA animal picornaviruses and plant comoviruses, which have a common genome organization. The structures of several human rhinovirus (HRV) serotypes (common cold virus) are 320 Å diameter particles with the VP1, VP2, and VP3 capsid subunits in a $T = 3$-like IAU (**Figure 8**). These subunits all have the β-barrel fold oriented tangentially and similar overall structure except for some loops and extended protein termini. The exterior of the particle has a deep cleft circling the fivefold axes (viral canyon) that binds the ICAM receptor on the surface of cells and which is also bound by neutralizing antibodies.

The capsid of the plant bean-pod mottle virus (BPMV) is also 320 Å in diameter, but has only two subunits, small and large. Both fold into β-barrel domains: one in the small subunit and two that remain covalently attached in the large subunit. The subunits assemble into a $T = 3$-like shell such that the small subunit is equivalent to VP1, and the large subunit to VP2 and VP3 in the HRV capsids. The BPMV structure had the first ordered protein–RNA interactions seen in an icoshedral virus. Seven ribonucleotides in a single RNA strand were visible inside the capsid shell near the icosahedral threefold axis in a shallow pocket formed by nine different segments from both domains of the large capsid protein. A few specific interactions and a larger number of nonbonded contacts bind the ordered RNA segment.

Other Icosahedral Particles with Uncommon Architectures

While shell arrangements other than T lattices are possible with multiple single or unique capsid proteins in the IAU, these are so far rare. The inner $T = 1$ shell of the BTVC is described above in the $T = 13$ virus section. A very similar $T = 1$ shell has been described for the 440 Å diameter dsRNA yeast L–A virus capsid structure, which also has two copies of the single 680 a.a. in the IAU. This arrangement is emerging as a common structure among the inner protein shells of dsRNA viruses that transcribe mRNA inside the particle and extrude the nascent strands through holes in the shell.

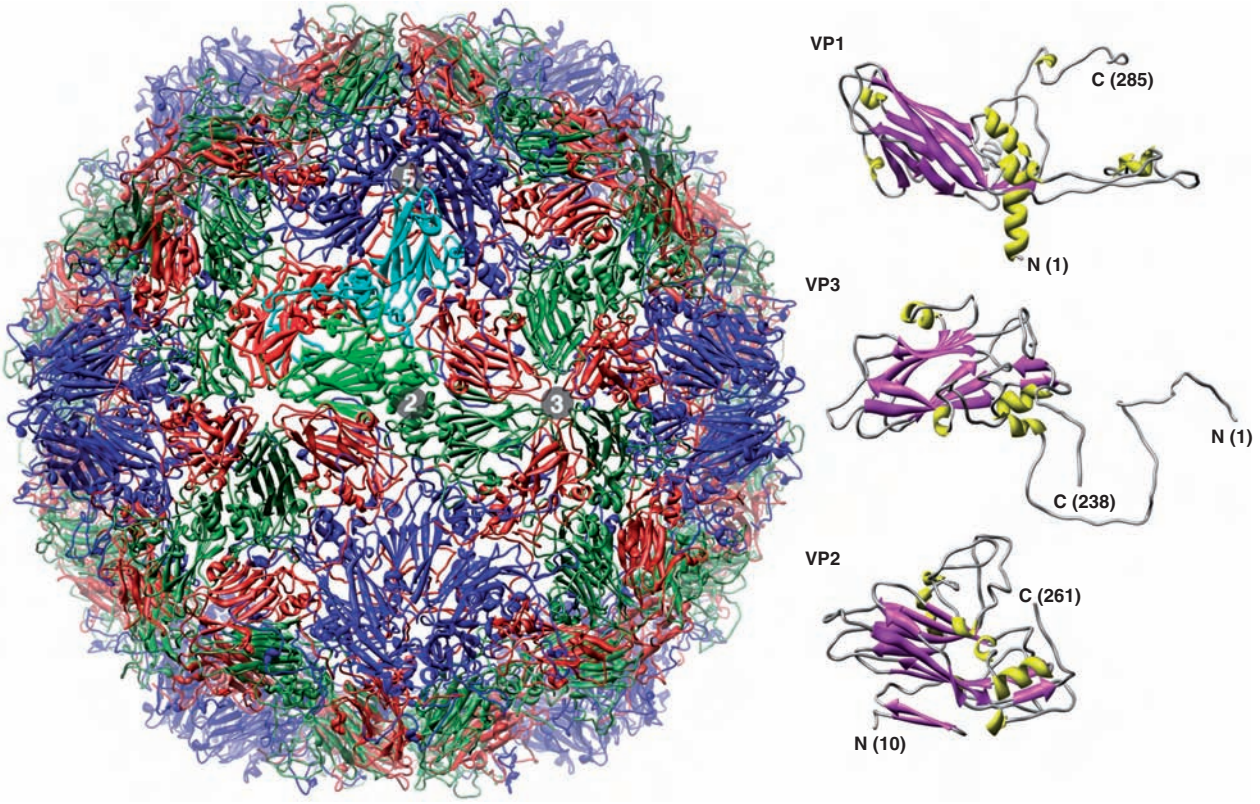

Figure 8 Structure of the $P = 3$ HRV-16 capsid viewed down an icosahedral twofold axis. Icosahedral axes are labeled as in **Figure 3**, but note there are is no quasi-symmetry since the proteins have unique primary structures. The VP1 proteins are colored blue, VP2 green, and VP3 red. An asymmetric unit is shown above and to the left of the twofold axis in brighter colors and larger ribbons (note the color and asymmetric unit definitions are a bit different than in $T = 3$ particles). Structures of the three different proteins are shown to the right and colored as in **Figure 2**. Note the slight tilt of the VP1 subunits that helps to create the canyon surrounding the pentamers.

Concluding Remarks

A great deal of our early knowledge of virus structure came from the nonenveloped viruses, and they continue to provide valuable data in understanding the virus life cycle. The important role of viruses in disease makes it imperative we understand the chemistry and biology of their capsids in ever greater detail. While some overall themes emerge, such as the general nature of capsid protein–protein interactions, protein–RNA interactions, and protein shell organizations, their remarkable variation and complexity defies attempts to form a comprehensive understanding of how they assemble and function. Recent structural evidence pointing to the existence of a primordial virus may lead to important new insights as virus structural studies address even more complex particles at an accelerated rate.

Introduction

The virion is a nucleoprotein particle designed to move the viral genome between susceptible cells of a host and between susceptible hosts. An important limitation on the size of the viral genome is its container, the protein capsid. The virion has a variety of functions during the virus life cycle (**Table 1**); however, the principles dictating its architecture result from the need to provide a container of maximum size derived from a minimum amount of genetic information. The universal strategy evolved for the packaging of viral nucleic acid employs multiple copies of one or more protein subunit types arranged about the genome. In most cases the subunits are arranged with well-defined symmetry, but there are examples where assembly intermediates and sometimes mature particles are not globally symmetric. The assembly of subunits into nucleoprotein particles is, in many cases, a spontaneous process that results in a minimum free energy structure under intracellular conditions. The two broad classes of symmetric virions are helical rods and spherical particles.

Helical Symmetry

The nucleoprotein helix can, in principle, package a genome of any size. Extensive studies of tobacco mosaic virus (TMV) show that protein subunits will continue to add to the extending rod as long as there is exposed RNA. Protein transitions required to form the TMV helix from various aggregates of subunits are now understood at the atomic level. It is clear that subunits forming the helix display significant polymorphism in the course of assembly; however, excluding the two ends of the rod, all subunits are in identical environments in the mature helical virion. This is the ideal protein context for a minimum free energy structure. In spite of these packaging and structural attributes the helical virion must be deficient in functional requirements that are common for animal viruses because they are found only among plant, bacterial, and archeal viruses. Even among plant viruses, only 7 of the 25 recognized groups are helical. The large majority of all viruses are roughly spherical in shape.

Icosahedral Symmetry

The architectural principles for constructing a 'spherical' virus were first articulated by Crick and Watson in 1956. They suggested that identical subunits were probably distributed with the symmetry of Platonic polyhedra (the tetrahedron, 12 equivalent positions; the octahedron, 24 equivalent positions; or the icosahedron, 60 equivalent positions). Subunits distributed with the symmetry of the icosahedron (**Figure 1(a)**) provide the maximum sized particle, for a given sized subunit, in which all copies of a subunit lie in identical positions. The repeated interaction of chemically complementary surfaces at the subunit interfaces leads naturally to such a symmetric particle. The 'instructions' required for assembly are contained in the tertiary structure of the subunit (**Figure 1(b)**). The actual assembly of the protein capsids is a remarkably accurate process. The use of subunits for the construction of organized complexes places strict control on the process and will naturally eliminate defective units. The reversible formation of noncovalent bonds between properly folded subunits leads naturally to error-free assembly and a minimum free energy structure.

Table 1 Functions of the virus capsid in simple RNA viruses

Assembly	Subunits must assemble to form a protective shell for the RNA
Package	Subunits specifically package the viral RNA
Binding to receptors	The capsid may actively participate in virus infection processes binding to receptors and mediating cell entry (animal) and disassembly
Transport	Virion transport within the host (plant)
Mutation	Capsid protein mutation to avoid the immune system
RNA replication	Some capsid proteins function as a primer for viral RNA replication

Virus Structures

Crystallographic studies of nearly 90 unique, icosahedral viruses have demonstrated that there are a limited

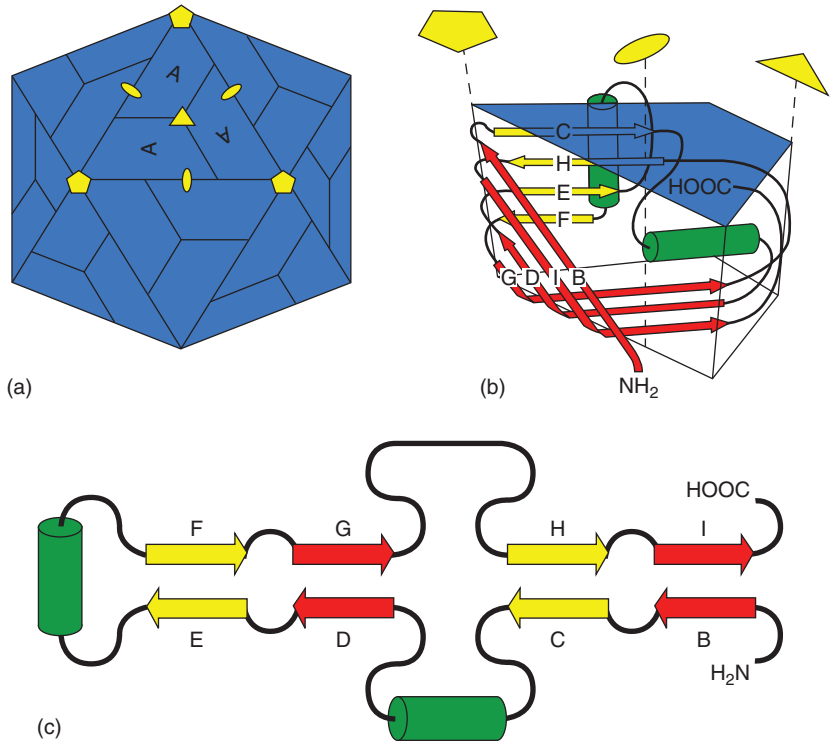

Figure 1 (a) The icosahedral capsid contains 60 identical copies of the protein subunit (blue) labeled A. These are related by fivefold (yellow pentagons at vertices), threefold (yellow triangles in faces), and twofold (yellow ellipses at edges) symmetry elements. For a given sized subunit this point group symmetry generates the largest possible assembly (60 subunits) in which every protein lies in an identical environment. (b) A schematic representation of the subunit building block found in many RNA and some DNA viral structures. Such subunits have complementary interfacial surfaces which, when they repeatedly interact, lead to the symmetry of the icosahedron. The tertiary structure of the subunit is an eight-stranded β-barrel with the topology of the jellyroll (see c-, β-strand and helix coloring is identical to b). Subunit sizes generally range between 20 and 40 kDa with variation among different viruses occurring at the N- and C-termini and in the size of insertions between strands of the β-sheet. These insertions generally do not occur at the narrow end of the wedge (B–C, H–I, D–E, and F–G turns). (c) The topology of viral β-barrel showing the connections between strands of the sheets (represented by yellow or red arrows) and positions of the insertions between strands. The green cylinders represent helices that are usually conserved. The C–D, E–F, and G–H loops often contain large insertions.

number of folds utilized in forming viral capsids. By far the most common fold is the eight-stranded antiparallel β-sandwich shown schematically in **Figure 1**(**b**). The details of all the folds observed in nonenveloped virus capsids and their distribution are discussed elsewhere in this encyclopedia.

Early ideas explaining spherical virus architecture were extended on the basis of physical studies of small spherical RNA plant viruses. The large yields and ease of preparation made them ideal subjects for investigations requiring substantial quantities of material. Protein subunits forming virus capsids of this type are usually 20–40 kDa. An example of a virus consistent with the Crick and Watson hypothesis is satellite tobacco necrosis virus (STNV) which is formed from 60 identical 25 kDa subunits. The particle's outer radius is 80 Å and the radius of the internal cavity is 60 Å providing a volume of 9×10^5 Å^3 for packaging RNA. A single hydrated ribonucleotide in a virion will occupy on average roughly 600–700 Å^3. Thus, the STNV volume is adequate to package a genome of only 1200–1300 nt. STNV is a satellite virus and the packaged genome codes for only the coat protein. The 'helper virus', tobacco necrosis virus, supplies proteins required for RNA replication. Most simple ribovirus genomes contain coding capacity for at least two proteins; roughly, 1200 nt for the capsid protein and 2500 nt for an RNA-directed RNA polymerase. The inner radius required to package such a minimal genome is 90 Å. Consistent with this requirement were experimental studies showing that the vast majority of simple spherical viruses had outer radii of at least 125 Å, which corresponds to inner radii of roughly 100 Å for a typical shell thickness for a 400 residue subunit. Such particles had to be formed from more than 60 subunits, yet X-ray diffraction patterns of crystalline tomato bushy stunt virus (TBSV) and turnip yellow mosaic virus (TYMV) were consistent with icosahedral symmetry.

Quasi-Equivalent Virus Capsids

Although a number of investigators developed hypotheses explaining the apparent inconsistent observations, Caspar and Klug, in 1962, derived a general method for the construction of icosahedral capsids that contained multiples of 60 subunits. The method systematically enumerates all possible quasi-equivalent structures and is similar to that derived by Buckmeister Fuller to construct geodesic domes. The quasi-equivalent theory of Caspar and Klug explained the distribution of morphological units (features identifiable at low resolution by electron microscopy often corresponding to hexamer, pentamer, trimer, or dimer aggregates of the subunits) on all structures observed to date, but the results from high-resolution crystallographic studies have shown some remarkable inconsistencies with the microscopic principles upon which the theory is based.

Quasi-equivalence is best visualized graphically. Formally, subunits forming quasi-equivalent structures must be capable of assembling into both hexamers (which are conceptually viewed as planar) and pentamers (which are convex because one subunit has been removed from the planar hexamer and yet similar (quasi-equivalent) contacts are maintained). Caspar and Klug proposed that, logically, atomic interactions of fivefold-related and sixfold-related subunits could be closely similar, as only the dihedral angle between subunits would change. They argued that this difference could be accommodated by allowed variations in noncovalent bond angles between residues stabilizing the oligomers. This prediction was correct for some virus capsids, as illustrated below for cowpea chlorotic mottle virus (CCMV), but in many viruses there is an explicit molecular switch that changes the oligomeric state. If subunits assembled as all hexamers the result would be a sheet of hexamers and a closed shell could not form (**Figure 2**(**a**)). The rules of quasi-equivalence described a systematic procedure for inserting pentamers into the hexagonal net in such a way as to form a closed shell with exact icosahedral symmetry. **Figure 2** illustrates this principle and the selection rules for inserting pentamers. **Figure 3** illustrates how the morphogenesis of such an assembly may occur using the crystallographic structure of CCMV as inspiration. CCMV was the first virus structure determined that agreed in detail with the predictions of Caspar and Klug.

The quasi-equivalence theory has been universally successful in describing surface morphology of spherical viruses observed in the electron microscope and, prior to the first high-resolution crystallographic structure of a virus, it was assumed that the underlying assumptions of Caspar and Klug were essentially correct. The structure of TBSV determined at 2.9 Å resolution revealed an unexpected variation from the concept of quasi-equivalence which was defined as "any small, non random, variation in a regular bonding pattern that leads to a more stable structure than does strictly equivalent bonding." Unlike CCMV, the structure of TBSV showed that differences occurring between pentamer interactions and hexamer interactions were not small variations in bonding patterns, but almost totally different bonding patterns. **Figure 4** shows diagrammatically the subunit interactions in the shell of TBSV, SBMV, BBV, and TCV. These high-resolution structures revealed that the mathematical concept of quasi-equivalence predicted surface lattices accurately, but not for the reasons expected. Bonding contacts between quasi-threefold-related subunits are maintained with little deviation from exact symmetry while quasi-twofold contacts and icosahedral twofold contacts (which are predicted to be very similar) are quite different. The hexamer quasi-symmetry is better described as a trimer of dimers in the TBSV and related structures. Unlike the conceptual model and the CCMV capsid, the particle curvature in TBSV results from both pentamers and hexamers.

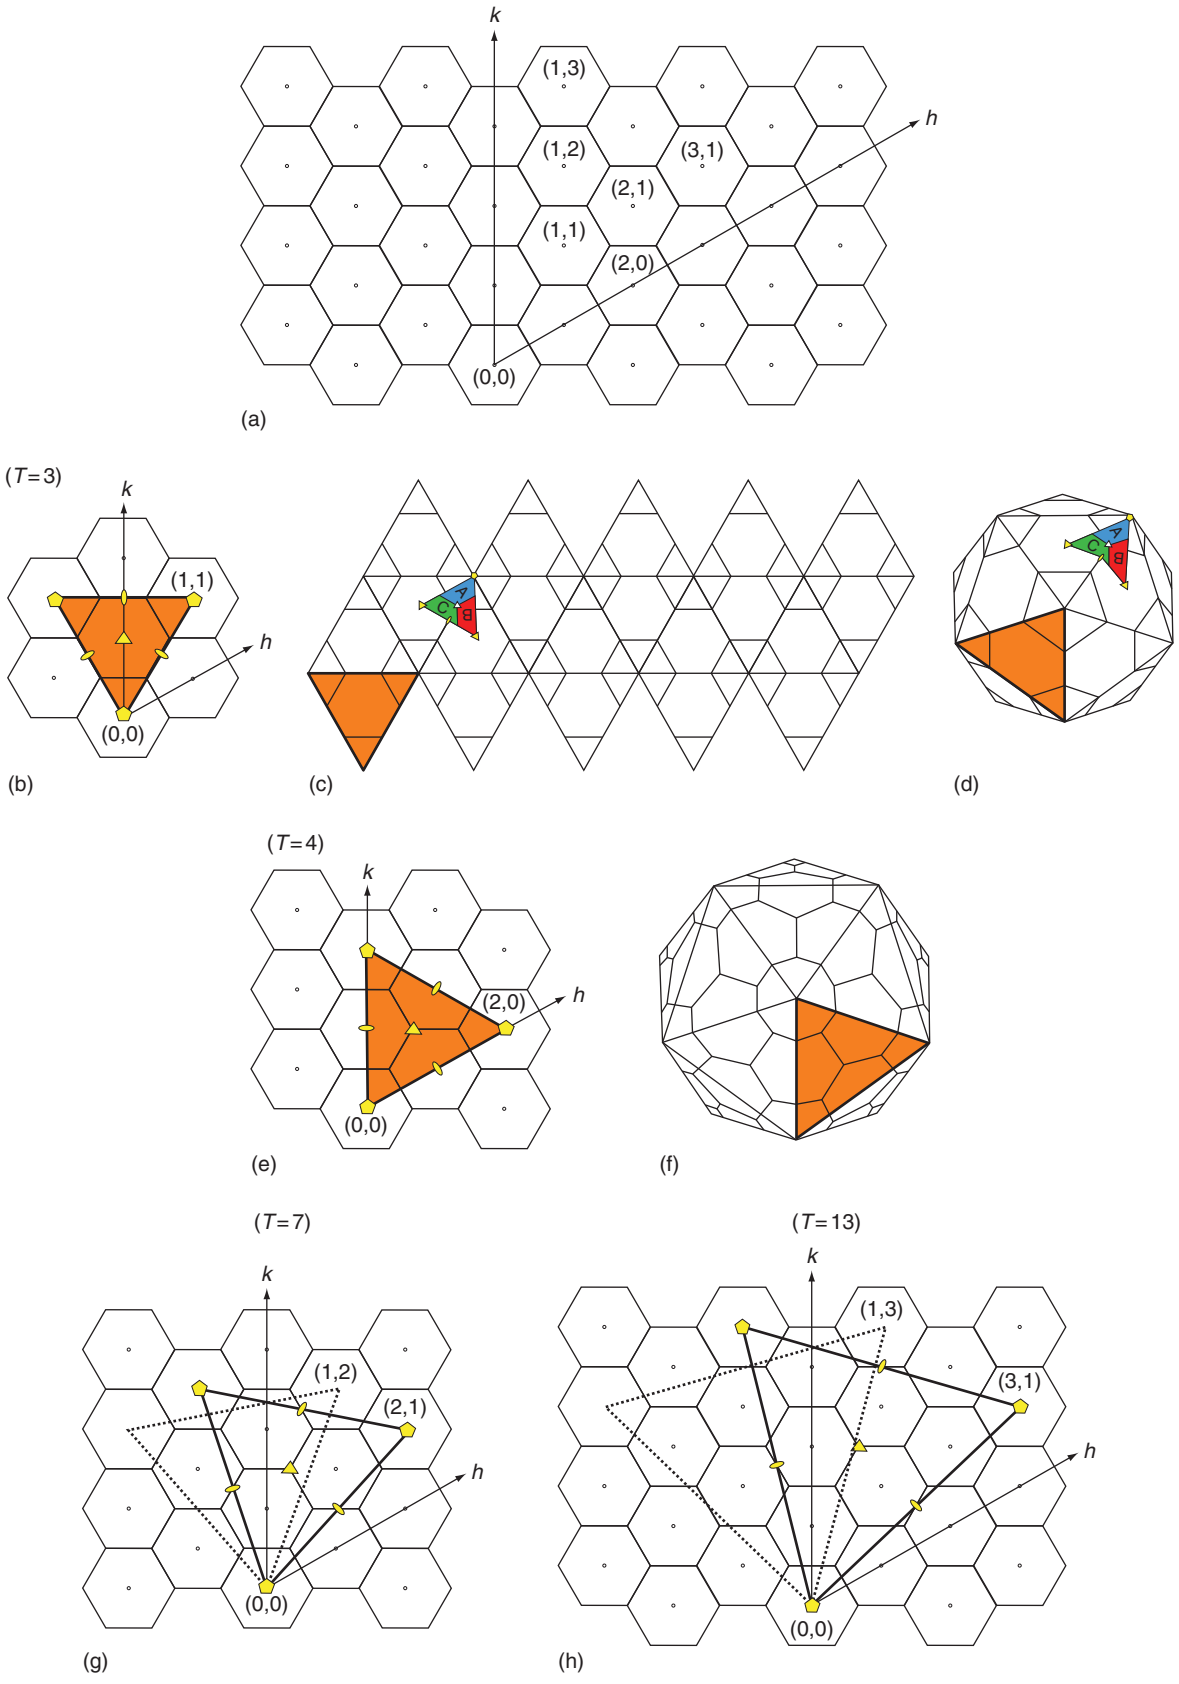

Figure 2 Continued

The high-resolution $T = 3$ structures showed that the overall features of the quasi-equivalent theory were correct, but the underlying concepts of quasi-equivalent bonding had to be revised. The first low-resolution structure (22.5 Å) of a $T = 7$ virus required an even greater conceptual adjustment to the underlying principles of quasi-equivalence. Rayment, Baker, and Caspar reported, in 1982, that the polyomavirus capsid contained 72 capsomers as previously reported from electron microscopy studies, but that all the capsomers were pentamers of protein subunits even when they were located at hexavalent lattice points. The $T = 7$ surface lattice predicts 12 pentamers and 60 hexamers; thus, the prediction of the number and position of the morphological units is correct, but the fine structure of the morphological units is incorrect. Although the result was highly controversial when first reported, additional electron microscopy studies and the 3.5 Å resolution X-ray structure of polyomavirus have fully confirmed the all-pentamer structure. This result clearly shows the limits of theory in predicting virus structure and indicates that further understanding of capsid structure will come only from experimental studies. The structure of the polyomavirus and its relatives illustrates an important concept when considering surface lattice formation. The feature of greatest importance is not the symmetry of the morphological unit positioned on the hexamer sites, but only its ability to accommodate six neighbors (it is a hexavalent position). Normally morphological units with sixfold symmetry accomplish this, but here, rather acrobatic molecular switching has permitted a pentamer of subunits to accommodate six neighbors. Although the all pentamer capsid has been observed for the $T = 7$ structure of papilloma viruses, cauliflower mosaic virus appears to have the hexamer/pentamer distribution predicted by quasi-equivalent theory as do the $T = 7$ capsids of the lambda-like bacteriophage, HK97. A substantial number of complex virus structures have been determined by cryo-electron microscopy and the surface lattices agree well with the predictions of quasi-equivalence. Thus there is considerable confidence in the lattice assignments, but the capsomer structure and therefore number of subunits must be carefully confirmed.

Figure 2 Geometric principles for generating icosahedral quasi-equivalent surface lattices. These four constructions show the relation between icosahedral symmetry axes and quasi-equivalent symmetry axes. The latter are symmetry elements that hold only in a local environment. (a) It is assumed in quasi-equivalence theory that hexamers and pentamers (a hexamer contains six units and a pentamer contains five units) can be interchanged at a particular position in the surface lattice. Hexamers are initially considered planar (an array of hexamers forms a flat sheet as shown) and pentamers are considered convex, introducing curvature in the sheet of hexamers when they are inserted. Inserting 12 pentamers at appropriate positions in the hexamer net generates the closed icosahedral shell, composed of hexamers and pentamers. The positions at which hexamers are replaced by pentamers are defined by the indices h and k measured along the labeled axes. The values of (h,k) used in the following examples are labeled. To construct a model of a particular quasi-equivalent lattice, one face of an icosahedron (equilateral triangles colored orange in (b–f)) is generated in the hexagonal net. The origin (0,0) is replaced with a pentamer, and the (h,k) hexamer is replaced by a pentamer. The third replaced hexamer is identified by threefold symmetry (i.e., complete the equilateral triangle). Each quasi-equivalent lattice is identified by a number $T = h^2 + hk + k^2$ where h and k are the indices used above. T indicates the number of quasi-equivalent units in the icosahedral asymmetric unit. For the purpose of these constructions it is convenient to choose the icosahedral asymmetric unit as 1/3 of an icosahedral face defined by the triangle connecting a threefold axis to two adjacent fivefold axes. Other asymmetric units can be chosen such as the triangle connecting two adjacent threefold axes and an adjacent fivefold axis (see (c) and **Figure 4**). The total number of units in the particle is 60T, given the symmetry of the icosahedron. The number of pentamers must be 12 and the number of hexamers is $(60T - 60)/6 = 10(T - 1)$. (b) One face of the icosahedron for a $T = 3$ surface lattice is identified by the orange triangle with the bold outline. The yellow symmetry labels are the same as those defined in **Figure 1**. The hexamer replaced has coordinates $h = 1$, $k = 1$. The icosahedral asymmetric unit is 1/3 of this face and it contains three quasi-equivalent units (two units from the hexamer coincident with the threefold axis and one unit from the pentamer). (c) Arranging 20 identical faces of the icosahedron as shown can generate the three-dimensional model of the quasi-equivalent lattice. Three quasi-equivalent units labeled A (blue), B (red), and C (green) are shown. These correspond to the three quasi-equivalent units defined in **Figures 3** and **4** rather than the alternative definition used in (a) and (b). (d) The folded icosahedron is shown with hexamers and pentamers outlined. The orange face represents the triangle originally generated from the hexagonal net. The $T = 3$ surface lattice represented in this construction has the appearance of a soccer ball. The trapezoids labeled A, B, and C identify quasi-equivalent units in one icosahedral asymmetric unit of the rhombic triacontahedron discussed in **Figure 4**. (e) An example of a $T = 4$ icosahedral face ($h = 2$, $k = 0$). In this case the hexamers are coincident with icosahedral twofold axes. (f) A folded $T = 4$ icosahedron with the orange face corresponding to the face outlined in the hexagonal net. Note that folding the $T = 4$ lattice has required that the hexamers have the curvature of the icosahedral edges. (g) A single icosahedral face generated from the hexagonal net for a $T = 7$ lattice. Note that there are two different $T = 7$ lattices ($h = 2$, $k = 1$ in bold outline; and $h = 1$, $k = 2$ in dashed outline). These lattices are the mirror images of each other. To fully define such a lattice, the arrangement of hexamers and pentamers must be established as well as the enantiomorph of the lattice. (h) A single icosahedral face for a T=13 lattice is shown. The two enantiomorphs of the quasi-equivalent lattice ($h = 3$, $k = 1$ – bold; and $h = 1$, $k = 3$ – dashed) are outlined. The procedure for generating quasi-equivalent models described here does not exactly correspond to the one described by Caspar and Klug in 1962. Caspar and Klug distinguish between different icosadeltahedra by a number $P = h^2 + hk + k^2$ where h and k are integers that contain no common factors but 1. The deltahedra are triangulated to different degrees described by an integer f that can take on any value. In their definition $T = Pf^2$. The description in this figure has no restrictions on common factors between h and k; thus, $T = h^2 + hk + k^2$ for all positive integers. The final models are identical to those described by Caspar and Klug.

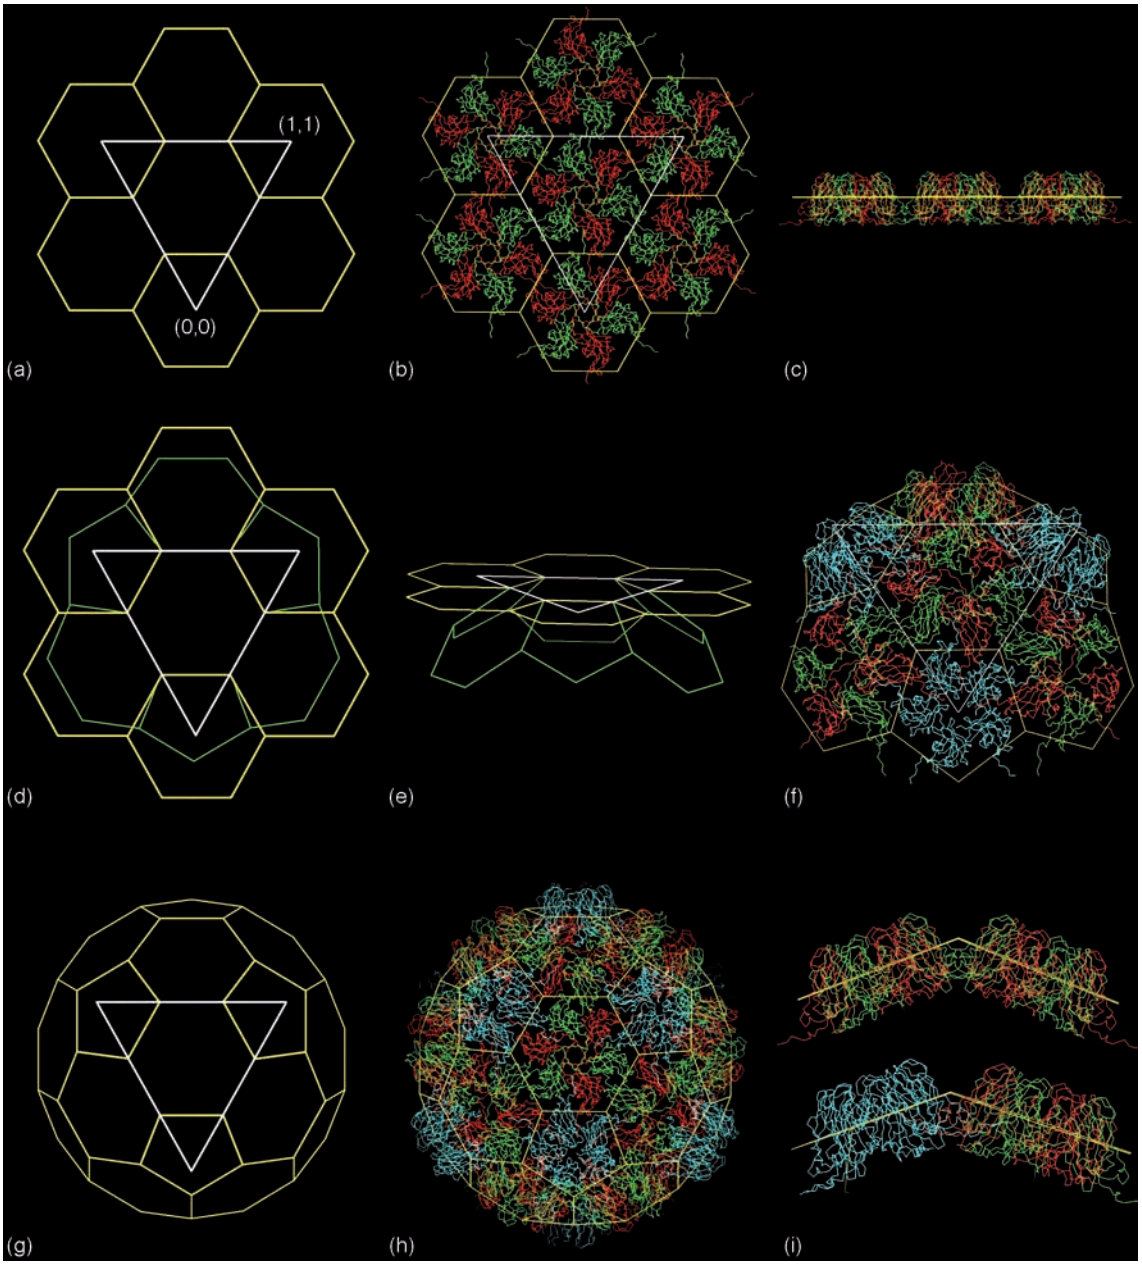

Figure 3 Molecular graphics construction of a $T = 3$ quasi-equivalent icosahedron. (a) Hexagonal sheet overlaid with the triangular coordinates (white) for a theoretical $T = 3$ quasi-equivalent icosahedron ($h = 1$, $k = 1$, see **Figure 2**(**b**)). The sheet has true sixfold rotational symmetry about axes passing through the hexamer centers, which are normal to the sheet. (b) Copies of the hexamer coordinates from the CCMV X-ray structure (colored by asymmetric unit position, see **Figures 2**(**c**)–**2**(**d**) and **4**) can be positioned in the sheet by simple translations. (c) A side view of the modeled sheet demonstrates its planarity. (d) Hexamers at the corners of the white ($h = 1$, $k = 1$) triangle become pentamers. The planar sheet (yellow model) takes on curvature to maintain contacts between the polygons (green model). (e) The magnitude of the pentamer-induced curvature is displayed in the side view of the partial polyhedron. (f) Coordinates of the CCMV X-ray structure fit this construction without any manipulation. (g) A completed $T = 3$ icosahedral model. The 12 pentamers generate curvature that closes the structure. This cage (a truncated icosahedron) accurately describes the geometric morphology of CCMV (h) which is composed of modular, planar, pentamers (12) and hexamers (20). Angular pentamer–hexamer and hexamer–hexamer interfaces (i) stabilize curvature in the absence of convex pentamers used to construct the soccer ball of **Figure 3**(**d**) (see also **Figure 4**).

Picorna-Like Virus Capsids

A number of viral capsids are constructed with pseudo $T = 3$ symmetry. These structures contain β-barrel subunits (**Figure 1**(**b**)) in the quasi-equivalent environments formed in $T = 3$ structures, but each of the three β-barrels in the asymmetric unit has a unique amino acid sequence. Rather than 180 identical subunits, the $P = 3$ particles contain 60 copies each of three different subunits (**Figure 5**). These structures do not require quasi-equivalent bonding

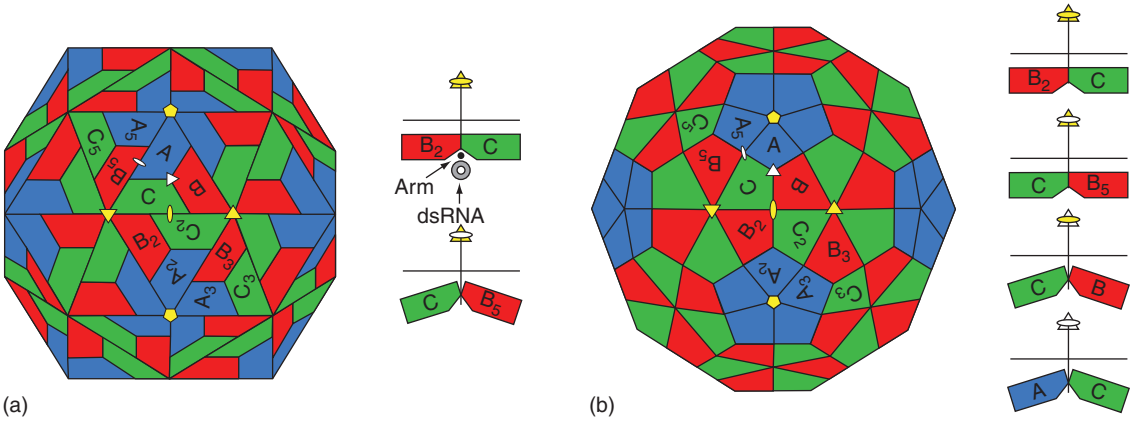

Figure 4 Although quasi-equivalence theory can predict, on geometrical principles, the organization of hexamers and pentamers in a viral capsid, the detailed arrangement of subunits can only be established empirically. High-resolution X-ray structures of $T = 3$ plant and insect viruses show that the particles are organized like the icosahedral rhombic triacontahedron or truncated icosahedron. A convenient definition of the icosahedral asymmetric unit for both geometrical shapes is the wedge defined by icosahedral threefold axes left and right of the particle center and an icosahedral fivefold axis at the top. The icosahedral asymmetric unit contains three subunits labeled A (blue), B (red), and C (green) (see **Figures 2(c)–2(d)**). The asymmetric unit polygons represent chemically identical protein subunits that occupy slightly different geometrical (chemical) environments as indicated by differences in their coloring. Polygons with subscripts are related to A, B, and C by icosahedral symmetry (i.e., A to A_5 by fivefold rotation). The shapes of the $T = 3$ soccer ball model in **Figure 2(d)**, truncated icosahedron in **Figure 3**, and rhombic triacontahedron are all different; however, the quasi-symmetric axes are in the same positions relative to the icosahedral symmetry axes for all three models. Quasi-threefold and quasi-twofold axes are represented by the white symbols. The quasi-sixfold axes are coincident with the icosahedral threefold axes in $T = 3$ particles as shown in **Figures 2(b)–2(d)** and **3**. (a) The rhombic triacontahedron is constructed by placing rhombic faces perpendicular to icosahedral twofold symmetry axes (yellow ellipse). Thus, the A, B, and C polygons are co-planar within each asymmetric unit. The shape of the subunit in $T = 3$ plant and insect viruses is nearly identical to the shape of the subunit in the $T = 1$ virus and they pack in a very similar fashion. The $T = 1$ subunits in one face (**Figure 1(a)**) are related by an icosahedral threefold axis while the $T = 3$ subunits in one face are related by a quasi-threefold axis. The dihedral angle between subunits C and B_5 (juxtaposed across quasi-twofold axes) is 144° and is referred to as a bent contact (bottom right image), while the dihedral angle between subunits C and B_2 (juxtaposed across icosahedral twofold axes) is 180° and is referred to as a flat contact (top-right image). Two dramatically different contacts between subunits with identical amino acid sequences are generated by the insertion of an extra polypeptide from the N-terminal portion of the A or C subunits into the groove formed at the flat contact. This polypeptide is called an 'arm'. The flat contact can also be upheld by insertion of nucleic acid structure into the same groove. Neither N-terminal arms nor nucleic acid structure has been observed in the groove across the quasi-twofold axis; thus, C and B_5 are in direct contact as in, for example, the X-ray structure of flock house virus (FHV). (b) A truncated icosahedron achieves curvature at different interfaces compared to the rhombic triacontahedron. Interactions between B_2–C and between C–B_5 polygons are both defined by 180° dihedral angles (side view at top right), whereas bends similar in magnitude occur within the asymmetric unit at the B–C and C–A polygon interfaces (138° and 142°, respectively; side view at bottom right). This creates the planar pentamer and hexamer morphological units characteristic of the truncated icosahedron and the CCMV X-ray structure (**Figure 3(h)**).

because each unique interface will have different amino acids interacting, rather than the same subunits forming different contacts. The animal picornaviruses have capsids of this type. Animal virus capsids undergo rapid mutation which avoids recognition by the circulating immune system. Capsids composed of three subunit types could mutate in one subunit without affecting the other two. This would be less likely to affect assembly or other functions of the particle in $P = 3$ shells than it would in $T = 3$ shells. At least one plant virus group displays $P = 3$ shells, the comoviruses. An interesting variation occurs in these capsids when compared with the picornaviruses. Two of the domains forming the shell are contained in a single polypeptide chain. This phenomenon is readily understood in the context of the synthesis of the subunits in picorna and comoviruses. In both cases the proteins are synthesized as a polyprotein that is subsequently cleaved into functional proteins by a virally encoded protease. Clearly one of the cleavage sites in picornaviruses is missing in the comoviruses, resulting in these two domains being still a 'polyprotein'. Tobacco ringspot virus (TRV) is an example where all three subunits are linked in a single polypeptide chain like 'beads on a string'. It is interesting to note that the X-ray structure of TRV showed that the linkage of subunits in the capsid is the same as that predicted for the precursor polyprotein of picornaviruses based on the their X-ray structures, supporting the divergent evolution of the $P = 3$ capsids from plant viruses to animal viruses.

Virus Particle Maturation

While $T = 3$ and $P = 3$ animal viruses undergo maturation processes that confer infectivity, there is little change in their particle morphology during this process.

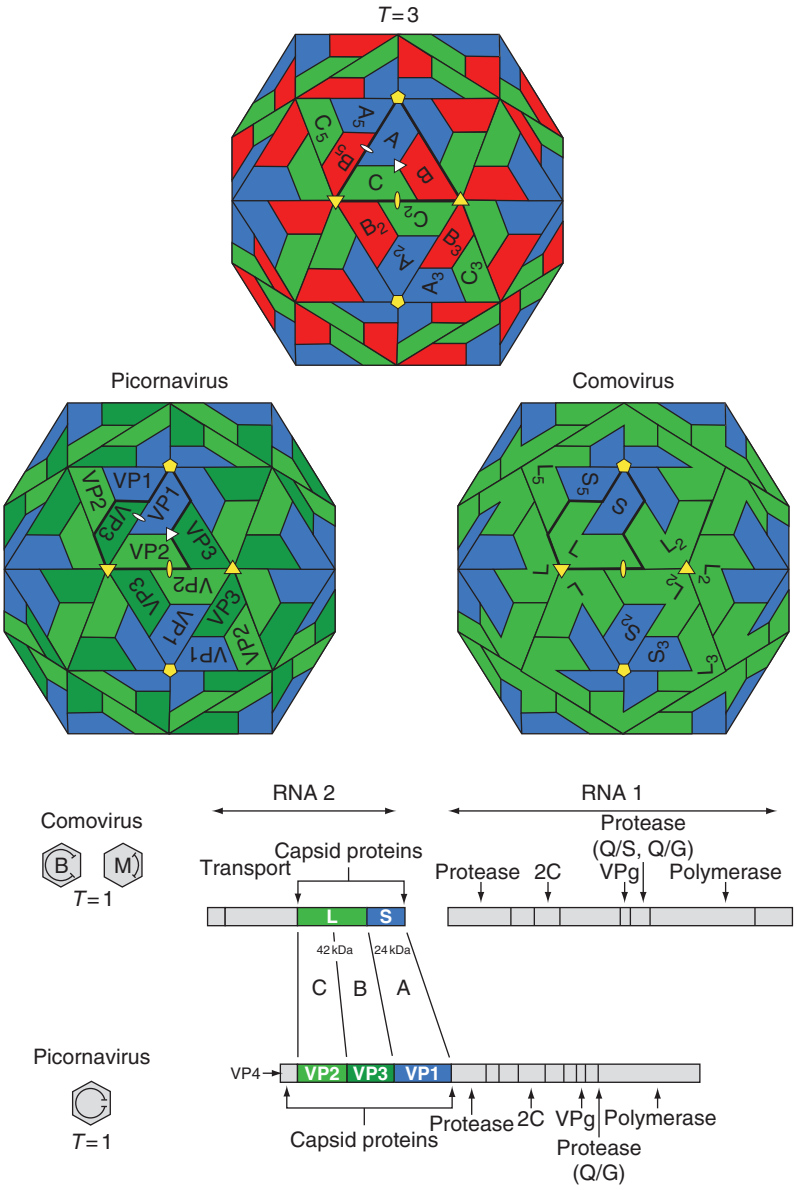

Figure 5 A comparison of $T = 3$, picornavirus, and comovirus capsids. In each case, one trapezoid represents a β-barrel and the icosahedral asymmetric units are outlined in bold. The icosahedral asymmetric unit of the $T = 3$ shell contains three identical subunits labeled A, B, and C (see **Figure 4**). The asymmetric unit of the picornavirus capsid contains three β-barrels, but each has a characteristic amino acid sequence labeled VP1, VP2, and VP3. The comovirus capsid is similar to the picornavirus capsid except that two of the β-barrels (corresponding to the green VP2 and VP3 units) are covalently linked to form a single polypeptide, the large protein subunit (L), while the small protein subunit (S) corresponds to VP1 (note the similar color shading). The individual subunits of the comovirus and picornavirus capsids are in identical geometrical (chemical) environments (e.g., VP1 and S are always pentamers) technically making these $T = 1$ capsids, but they are often referred to as pseudo $T = 3$, or $P = 3$ capsids. Comoviruses and picornaviruses have a similar gene order, and the nonstructural 2C and polymerase genes display significant sequence homology. The relationship between the capsid subunit positions in these viruses and their location in the genes is indicated by color-coding and the labels A, B, and C in the gene diagram.

In contrast, bacteriophages, such as HK97, display dramatic subunit reorganization during maturation. (The head (capsid) of the HK97 bacteriophage first assembles as a metastable prohead (prohead I and II), and then undergoes a complex maturation process that involves large-scale macromolecular transitions that expand the protein shell. There are three well-defined expansion intermediates (EI-I/II, EI-III, EI-IV) that end with the EI-IV state, which is the final step before head maturation is complete. The crosslinks between the 420 subunits are formed during these steps, except for the last 60 situated around the 12 pentamers. Formation of the final 60 crosslinks is the final step that creates head II, the mature capsid.) The X-ray structure of mature HK97 showed that each subunit in the $T = 7l$ capsid makes contact with nine other subunits, displaying molecular

promiscuity at an unprecedented level. These interactions, together with covalent cross-links between subunits create an exceptionally stable particle. It is clear, however, that such a structure cannot be achieved in a single step. It is too complicated. The solution is to assemble in stages. The initial assembly product is called a procapsid. This is formed by three gene products: 415 copies of the capsid protein, 12 copies of the portal subunit, and about 60 copies of a virally encoded protease that is inside the 500 Å diameter particle. This is an equilibrium assembly that is similar to the assembly of simpler viruses. Subunits are confined to discrete volumes and contact only immediate neighbors, again, as observed with simple viruses. Completion of assembly signals protease activation, and 103 residues are cut from each capsid protein and the protease auto-digests, leaving an empty particle that is a substrate for DNA packaging enzymes. When the terminase complex, also virally encoded, attaches to the double-stranded DNA viral genome and the portal, DNA packaging ensues and after ~10% of the DNA is packaged, the particle undergoes an extraordinary reorganization involving 40° rotations of subunits and 40 Å translations, totally remodeling the contacts resulting in the highly interlocked structure in the mature virion. Maturation of this type is entirely programmed into the original tertiary and quaternary structures and is an excellent example of a molecular machine.

Concluding Remarks

This overview of virus structure and assembly illustrates the remarkable level of sophistication associated with one or a few gene products acting in concert. The requirement for maximum utility from minimal genetic information has led to the evolution of proteins with exceptionally high functional density that are studied to develop better understanding of virus-associated disease and as accessible paradigms for cellular function.

Glossary

Ecological niche The ecological niche of a virus refers to certain biological properties of the virus, such as host range, tissue tropism in the host, and type of vector, rather than a geographical space or a particular environment. In the absence of the virus, its ecological niche property is also absent and the notion of a vacant niche is thus meaningless.

Polythetic class A polythetic class consists of members that exhibit overall similarity and have a large number of common properties. However, the members of a polythetic class do not all share a common character that constitutes a single defining property of the class. In contrast, the members of a monothetic class, such as those of the order *Mononegavirales*, possess such a single defining property, that is, the presence of a negative-sense, single-stranded RNA (ssRNA) genome.

Introduction

The question of what is a virus species is related to the general problem of how the world of viruses should be partitioned and ordered for achieving a coherent scheme of distinct and easily recognizable viral entities. In view of the variability of viruses arising from the error-prone process of genomic replication, it is often difficult to decide whether a newly encountered virus is the same as one seen previously, for this requires that we give an answer to the vexing question: "How different must two virus isolates be in order to be considered different viruses, rather than the same virus?" Virologists usually have no difficulty in distinguishing pathogenic variants of a virus, while still recognizing these variants as the same kind of virus. Even without realizing it, they pass judgment on the significance of the observed differences between individual virus isolates and, if the extent of difference appears small enough, they will consider the variant to be the same virus. In taxonomic parlance, they will say that the variant belongs to the same virus species.

'Species' is the universally accepted term for the lowest taxonomic clustering of living organisms. Although viruses are not organisms, they are considered to be biological entities because they possess some of the properties of biological agents, such as having a genome and being able to adapt to particular hosts and changing environments. The classification system of viruses therefore uses the same hierarchical ranks of order, family, genus, and species used in all biological classifications.

Although the species category is the most fundamental one in any biological classification, it took many years before virologists started to assign viruses to separate species. Virus genera and families were readily accepted but there was considerable opposition to the idea that the species concept could be applied to viruses. One reason for this reluctance was the lack of agreement among biologists about what a species actually is. It is in fact remarkable that a century and a half after the appearance of Charles Darwin's *The Origin of Species*, there is still no general agreement about what constitutes a plant, animal, or microbial species. In different branches of biology, no less than 22 different species concepts have been applied.

Distinguishing between Abstract Classes and Real Objects

A basic requirement for clear thinking is the ability to distinguish between real, tangible objects, such as viruses, and the abstract classes used in taxonomy, such as families and species, which are mental constructs that exist only in the minds of people who think about them. Although a taxonomic class is defined by properties possessed by concrete objects, it is only an abstract thought that has no real existence outside of human minds. For this reason, viral species, genera, and families cannot cause diseases and cannot be purified, sequenced, or seen through electron microscopes. Only the viruses themselves can be studied in this manner. Classes used in biological classification have a hierarchical structure. A class, such as a particular species, can belong only to one higher rank immediately above it such as a particular genus and that genus, in turn, can only belong to one family. The relationship known as 'class membership' is the relationship between an abstract class or thought and the members of that class which are real, concrete objects located in space and time. Class membership is thus able to bridge two different logical categories, the abstract and the concrete. It is important to be able to establish a certain link between these two logical categories, as it is impossible for an object such as a virus to be 'part' of an abstraction, such as a species. Similarly, an abstract thought cannot be 'part of' a concrete object. The correct statement is to say that the viruses that are handled by virologists are members of certain abstract constructs, such as species or genera. These constructs are invented by taxonomists for the purpose of introducing some order to the bewildering variety of viruses.

A universal class, also known as an Aristotelian class, is defined by properties that are constant and immutable. This allows members of such a class to be recognized with absolute certainty, because one or more property is necessarily present in every member of the class. Virus families, for instance, are universal classes because they consist of members, all of which share a number of defining properties that are both necessary and sufficient for class membership. Allocating a virus to a family is thus an easy task, because a few structural or chemical attributes will suffice to allocate the virus to a particular family. For instance, all the members of the family *Adenoviridae* are nonenveloped viruses that have an icosahedral particle and double-stranded DNA, with projecting fibers at the vertices of the protein shell.

Unfortunately, not all properties of members of classes correspond to unambiguous and stable properties such as the presence or absence of a DNA genome or of a particular particle morphology. Many qualitative properties of concrete objects are inherently vague and do not possess precise borderlines. For instance, in the description of viruses, properties used for recognizing members of species, such as the degree of genome sequence similarity between virus isolates or the nature of the symptoms induced by a virus in its host, whether mild or severe, tend to be inherently imprecise and fuzzy. As a result the species classes that can be conceptualized on the basis of such properties will themselves be fuzzy and membership in the class will then be a matter of convention or stipulation. This explains some of the difficulties one encounters when dealing with the species level in any biological classification.

When fuzziness is accepted as an unavoidable characteristic of species, it becomes possible to describe species in terms of continuums with hazy boundaries. In a similar way, colors can be distinguished conceptually in spite of the continuous nature of the spectrum of electromagnetic waves, and mountain peaks are given names in spite of the absence of sharp boundaries in geological rock formations.

Species in Biology

The traditional view of species is that they correspond to groups of similar organisms that can breed among themselves and produce fertile offspring. The classical definition of so-called 'biological species' states that "species are groups of interbreeding natural populations which are reproductively isolated from other such groups." The reproductive isolation often simply reflects a geographic isolation or a behavioral incompatibility. This definition is only applicable to organisms that reproduce sexually and it has limited value in the plant kingdom because of the high frequency of hybridization between different species of plants. Even in animals, the criterion of reproductive isolation does not always hold, as shown by the ability of dogs, wolves, and coyotes to interbreed although they are members of different species of the same genus.

In order to make the definition of biological species applicable to asexual organisms, it was later modified as follows: "a species is a reproductive community of populations, reproductively isolated from others, that occupies a specific niche in nature." Some authors reject the view that asexual organisms can form biological species but most biologists disagree with that view, as this would render the species concept inapplicable to a large portion of the biological realm.

Another species concept is that of evolutionary species, which has been defined as "a single lineage of ancestor–descendant populations which maintains its identity from other such lineages and which has its own evolutionary tendencies and historical fate." Such a concept does not provide any guidance on how far back in time a species can be traced. Life on Earth is a biological and historical continuum and it is as difficult to demarcate boundaries in time that would separate individual evolutionary species as it is to define clear-cut breeding discontinuities that would separate different biological species. These difficulties led to the view that species are similar to fuzzy sets with unclear boundaries and that it is impossible to draw sharp boundaries between them, as is done with universal classes such as genera and families. In practice this means that it is not possible to rely on a single defining property for differentiating between two species. This led to the proposal that species are so-called 'polythetic classes' defined by a combination of properties, each of which might occur outside any given class yet could be absent in a member of the particular class (**Figure 1**).

The members of a polythetic class exhibit overall similarity and have a large number of characters in common. However, in contrast to the members of a monothetic or universal class, they need not all share a common character that could be used as a defining property of the class. A polythetic class is actually a cluster concept based on the concept of family resemblance introduced in philosophy by Ludwig Wittgenstein.

What Is a Virus Species?

In the past, many virologists were opposed to the introduction of species in virus classification because they assumed that the only legitimate species concept was that of biological species defined by sexual reproduction, gene pools, and reproductive isolation. Such a concept is obviously not applicable to viruses that are replicated as clones. Another reason for the reluctance to adopt the species category in virus classification was the absence of a satisfactory definition of a virus species. Various definitions of virus species had been proposed over the years but none gained general acceptance. One definition, for instance, stated that "virus species are strains whose properties are so similar that there seems little value in giving them separate names." Such a definition is not very helpful as it simply replaces undefined species by undefined strains and suggests that attributing names to viruses is the same activity as constructing a taxonomy.

In 1991, the International Committee on Taxonomy of Viruses (ICTV), which is the body established by the International Union of Microbiological Societies to make decisions on matters of virus classification and

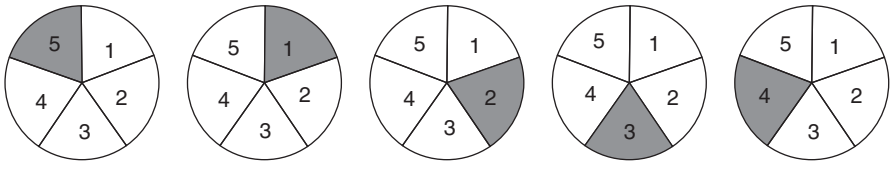

Figure 1 Schematic representation of the distribution of properties (1 to 5) in five members of a polythetic class. Each member possesses several of these properties (4 out of 5) but no single property is present in all the members of the class. The missing property in each case is represented by the gray section.

nomenclature, endorsed the following definition which was proposed by the author: "a virus species is a polythetic class of viruses that constitute a replicating lineage and occupy a particular ecological niche." This definition is not only based on phenetic similarities among members of species but also stresses the internal cohesion present in biological lineages that share a common biotic niche. Another important aspect of the definition is that a virus species is defined as a polythetic class rather than as a traditional universal class (see **Figure 1**). The ICTV has been using the concept of polythetic class for the creation of separate species taxa.

The total DNA or RNA sequence found in a virion corresponds to the viral genome and is part of the viral phenotype because it corresponds to a portion of the virion's chemical structure. The phenome of the virus corresponds to its observable physical properties, including the morphology and molecular constitution of the virion, as well as the biochemical activities and relational properties of the virus. The phenotype has a temporal dimension as it changes over time, for instance during replication.

A classification based on genome sequences is actually a phenotypic classification with the characters being molecular, rather than morphological or relational. Although putative phylogenetic relationships can be inferred from sequences, they remain tentative and depend on many tacit assumptions. There is little justification for the common assumption that when species are demarcated on the basis of a proposed phylogeny, this produces a classification that is necessarily more correct or useful than a classification based on other phenotypic characters.

Defining Species as a Taxonomic Class Is Not the Same As Demarcating Individual Viral Species

As a definition is the explanation of the meaning of a word or concept, it is possible to give a definition of the concept species. In contrast, it is not possible to give a definition of an object such as a particular virus, as objects can only be described by enumerating their properties and cannot be 'defined'. When viruses or any other object are given proper names, their names do not have a meaning that can be captured in a definition. When we define the name of an abstract species class by means of defining properties, we state the conditions for that name to apply to any given member of the species.

Two types of species definitions must be distinguished. One definition concerns the taxonomic species category corresponding to the lowest level in a hierarchical system of classification. The definition of virus species accepted by the ICTV is a definition of that type and it was introduced because many virologists thought that the species concept was not applicable to viruses. However, such a definition of the category species should not be confused with the definitions or demarcations of each of the 1950 species classes listed in the Eighth ICTV Report published in 2005. Confusing the two meanings of species, that is, as a particular class which has certain viruses as members and as a taxonomic category, respectively, would amount to confuse the concept of chemical element (the class of all elements) with the class corresponding to a single element, such as gold defined by its atomic number 79.

It must be emphasized that once the taxonomic category of virus species had been accepted by virologists, this did not do away with the difficult task of demarcating and defining the hundreds of individual species classes that had to be created on the basis of different combinations of properties for each polythetic species class. In order to demarcate individual species, it was necessary to rely on properties that were not present in all the members of the genus to which the species belongs, because such properties obviously would not permit individual species to be differentiated. Characteristics such as virion morphology, genome organization, method of replication, and number and size of viral proteins are shared by all the members of a genus and are thus not useful for distinguishing individual species in a genus. The properties that are useful for discriminating between individual species within a genus are the natural host range, cell and tissue tropism, pathogenicity, mode of transmission, certain physicochemical and antigenic properties of virions, and small differences in genome sequence. Unfortunately, these properties can be altered by only one or a few mutations and they may therefore vary in different members of the same species. This is one of the reasons species demarcation is not an easy task and often requires drawing boundaries across a continuous range of genomic and phenotypic variability. Taxonomic decisions at the level of species are very much a matter of opinion and adjudication rather than of logical necessity. There is indeed no precise degree of genome difference that could be used as a cutoff point to differentiate between two species nor is there a simple quantitative relationship between the extent of genome similarity and the similarity in phenotypic and biological characteristics of a virus.

There is also a strong subjective element in virus classification, as the practical need to distinguish between individual viruses is not the same in all areas of virology. From a human perspective, not all infected hosts are equally relevant. Human pathogens or pathogens that infect animals and plants of economic importance tend to be studied more intensively than the very many viruses that infect insects or marine organisms. As a result fine distinctions based on minor differences in host range or pathogenicity may be emphasized in the case of viruses of particular interest to humans and the criteria used for differentiating individual species may thus depend on

the type of host that is infected. There is, of course, no reason the criteria used for distinguishing between species should be the same in all the virus genera and families, because the need to make certain distinctions are not the same in all fields of virology.

Virus Identification

In order to identify a virus as a member of a species, use is made of so-called diagnostic properties that allow the virus to be recognized as being similar to other viruses. This, of course, means that the species had to be created and defined by taxonomists beforehand. Only when the properties of many members of an established species are compared, is it possible to discover which diagnostic property or set of properties will discriminate between the members of that species and other species, thereby allowing viruses to be identified. A single diagnostic character may sometimes suffice for virus identification but this character should not be confused with the collective set of combined properties which has been used initially to demarcate and define the species as a polythetic class. Species are not defined by means of one or more diagnostic properties used for virus identification but are defined by taxonomists, who stipulate which covariant sets of shared properties have to be present in most members of the species. It is the frequent, combined occurrence of these properties in individual members of a species that allows one to predict many of the properties of a newly discovered virus once it has been identified as a member of a particular species. If a species could be defined monothetically instead of polythetically, that is, by a single diagnostic character and nothing else, the identification of a virus as a member of a species would not be very informative. A single diagnostic character, such as a nucleotide motif or the reactivity with a monoclonal antibody, may suffice to identify a virus but such a property should not be mistaken for a single defining characteristic of the species.

This apparent contradiction between the need for many characters to define and delineate a species and the fact that a single property may suffice to identify a virus disappears when it is realized that defining an abstraction, such as a species, is a task different from identifying a concrete object, such as a virus. Providing a definition of an abstract taxonomic class and identifying concrete objects are not equivalent tasks and they abide by different logical rules.

Species Names and How to Write Them

After the category species was accepted as the lowest taxonomic class to be used in viral taxonomy, the ICTV decided in 1998 that the existing English common names of viruses were to become the official species names and that, to denote the difference, species names should be written in italics with a capital initial letter. This typography, which is similar to that used for other taxa such as virus genera and families, makes it possible to distinguish virus species officially recognized by the ICTV and written in italics from other viral entities such as tentative species and virus strains written in Roman characters.

When ICTV introduced italicized virus species names, it did not intend that the existing names of viruses written in Roman characters should be abandoned. In their writings, virologists need to refer continuously to the viruses they study and because these viruses are not taxonomic abstractions, their names should be written in Roman characters.

In most cases it is necessary only once in a scientific paper to draw attention to the taxonomic position of the virus and this can be done by mentioning that the virus under study, for example, measles virus, is a member of the species *Measles virus*, genus *Morbillivirus*, and family *Paramyxoviridae*. In publications written in languages other than English, the common names of the virus remain those used in that language. It will suffice, for instance, to say once: "le virus de la rougeole est un membre de l'espèce *Measles virus*."

It is correct to say that a virus, a strain, or an isolate of the species *Cucumber mosaic virus* has been sequenced but incorrect to say the species itself has been sequenced. Unfortunately, some authors confuse viruses with species and write that the species *Cucumber mosaic virus* (instead of the virus cucumber mosaic virus) has been isolated from a tobacco plant, is transmitted by an aphid vector, is the causal agent of a mosaic disease, and has been sequenced. This is of course incorrect because virus species are man-made taxonomic classes and do not have hosts, vectors, or sequences. For the same reason, the genus *Cucumovirus* or the family *Paramyxoviridae* cannot be isolated, visualized in an electron microscope, or sequenced.

At a time when English is more widely understood than Latin, the use of italicized English instead of italicized Latin for the names of virus species is more practical and is in line with the emergence of English as the modern language of international scientific communication. Most virologists are opposed to the Latinization of species names and welcomed the introduction of well-known English species names. They certainly preferred this to the creation of an entirely new set of Latin names for the 1950 different virus species that are recognized at present.

Binomial Names for Virus Species

A problem with the current way of naming virus species is that the name of the species (for instance *Measles virus*) differs only in typography from the name of the virus (measles virus). One way to facilitate the distinction

between virus names and species names would be to change the current names of virus species into nonlatinized binomial names. Such a system, which has been advocated by plant virologists for many years, consists in replacing the word '*virus*' appearing at the end of the existing species name by the genus name which also ends in '-*virus*'. *Measles virus* then becomes *Measles morbillivirus*, *Hepatitis A virus* becomes *Hepatitis A hepatovirus,* and *Tobacco mosaic virus* becomes *Tobacco mosaic tobamovirus*. The advantage of such a system, which could be implemented without problems for about 98% of all virus species names, is that inclusion of the genus name in the species name provides additional information about the properties of the virus. A changeover to binomial species names would not affect the common names of viruses in English or other languages since names such as measles virus or 'virus de la rougeole' would remain the same. The ICTV is currently debating the possibility of introducing binomial species names and some decision is likely to be made in the near future.

Given that the common names of viruses are used repeatedly in scientific texts there is a need for abbreviating them and the ICTV has published several lists of recommended acronyms for virus names. Since the names of virus species are used only very seldom in publications, there is no need to abbreviate them. If binomial names of virus species were introduced in the future, the abbreviations of common names of viruses will of course not be affected.

Viruses and Bioterrorism

R F Meyer and S A Morse, Centers for Disease Control and Prevention, Atlanta, GA, USA

Published by Elsevier Ltd.

Introduction

Man has known that biological organisms and toxins were useful as weapons of war long before the germ theory of disease was understood. However, as the twentieth century came to a close, the perceived difficulties in production, weaponization, and deployment of these biological weapons as well as a belief that moral restraints would preclude the use of these weapons gave many a false sense of security. Recently, a number of events have served to focus attention on the threat of terrorism and the potential for the use of biological, chemical, or nuclear weapons against the military, civilian populations, or agriculture for the purpose of causing illness, death, or economic loss. This possibility became a reality in October 2001 when someone sent spores of *Bacillus anthracis* to media companies in New York City and Boca Raton, Florida, resulting in five deaths, considerable panic throughout the United States and other countries, and raised the awareness of our vulnerability.

There are more than 1400 species of infectious organisms that are known to be pathogenic for humans; many additional organisms are capable of causing disease in animals or plants. Realistically, only a few of these infectious agents pose serious problems or are capable of affecting human, animal, or plant health on a large scale. Even fewer of these agents are viruses. Viruses that could be used as weapons against humans, animals, or plants generally possess traits including ease of production and dissemination, transmissibility, environmental stability, and high morbidity and mortality rates.

Definitions

The use of biological agents is often characterized by the manner in which they are used. For the purposes of this article 'biological warfare' is defined as a special type of warfare conducted by a government against a target; 'bioterrorism' is defined as the threat or use of a biological agent (or toxin) against humans, animals, or plants by individuals or groups motivated by political, religious, ecological, or other ideological objectives. Furthermore, terrorists can be distinguished from other types of criminals by their motivation and objective; however, criminals may also be driven by psychological pathologies and may use biological agents. When criminals use biological agents for murder, extortion, or revenge, it is called a 'biocrime'.

Historical Perspective

The use of viral agents for biological warfare has a long history, which predates their recognition and isolation by culture. Their early use is consistent with what, at the time, was known about infectious diseases, particularly smallpox. In the sixteenth century, the Spanish explorer, Francisco Pizarro, presented the indigenous peoples of South America with variola-contaminated clothing, which resulted in widespread epidemics of smallpox. During the French and Indian War (1745–67), Sir Jeffrey Amherst, commander of the British forces in North America, suggested the deliberate use of smallpox to 'reduce' Native American tribes hostile to the British. Captain Ecuyer (one of Amherst's subordinates), fearing an attack on Ft. Pitt from Native Americans, acquired two variola-contaminated blankets and a handkerchief from a smallpox hospital and, in a gesture of good will, distributed them to the Native Americans. As a result, several outbreaks of smallpox occurred in various tribes in the Ohio River valley. In 1775, during the Revolutionary War, the British attempted to spread smallpox among the Continental forces by inoculating (variolation) civilians fleeing Boston. In the South, there is evidence that the British were going to distribute slaves who had escaped during hostilities, and were sick with smallpox, back to the rebel plantations in order to spread the disease.

The use of viruses other than Variola major is a more recent phenomenon and reflects an increased knowledge of how to grow and stabilize viruses for delivery purposes. Allegations have been made by the government of Cuba that the CIA was responsible for the massive outbreaks of swine fever in 1971 and dengue fever in 1980 that ravaged the country. However, subsequent investigations have failed to find substantive proof of CIA involvement in these outbreaks. The Aum Shinrikyo, a religious cult responsible for the 1995 release of sarin gas in the Tokyo subway system, was also involved in biological warfare activity and sent a team of 40 people to Zaire to acquire Ebola virus. Fortunately, they were unsuccessful in this endeavor. In 1997, unknown farmers in New Zealand deliberately and illegally introduced rabbit hemorrhagic disease virus (a calicivirus) onto the south island as an animal control tool to kill feral rabbits.

Over the past two decades, the human immunodeficiency virus (HIV) has been involved in a number of biocrimes. This most likely reflects the availability of HIV-contaminated blood as a source of this virus. For example, in 1990, Graham Farlow, an asymptomatic HIV-positive inmate at a prison in New South Wales, Australia, injected a guard with HIV-contaminated blood. The guard became infected with HIV; Farlow subsequently died of AIDS. In 1992, Brian T. Stewart, a phlebotomist at a St. Louis, MO hospital, injected his 11-month-old son with HIV-contaminated blood during a fight over payment of child support. In 1993, Iwan E. injected his former girlfriend with 2.5 ml of HIV-contaminated blood after she broke up with him. In 1994, Dr. Richard J. Schmidt, a married Louisiana gastroenterologist, injected a former lover with HIV-contaminated blood. Molecular typing of the HIV strains demonstrated that she contracted the same strain of HIV as found in one of Dr. Schmidt's patients. In perhaps the most famous case, Dr. David Acer, a Florida dentist infected with HIV, transmitted the disease to six of his patients between 1987 and 1990. The intentional infection of these patients is a possibility although there is no direct evidence. In spite of these incidents, HIV has not been included on lists of threat agents for public health bioterrorism preparedness. However, some contend that HIV has great weapon potential if the goal is to destabilize a society.

Viruses have also been involved in suspected incidents or hoaxes. In 1999, an article appeared suggesting that the CIA was investigating whether Iraq was responsible for causing the outbreak of West Nile fever in the New York City area. The story relied heavily on a previous story written by an Iraqi defector, claiming that Saddam Hussein planned to use West Nile virus strain SV 1417 to mount an attack. The investigation indicated that there was no known evidence of bioterrorism involved in the spread of West Nile virus. A fictional 'virus' was also involved in one of the largest bioterrorism hoaxes in 2000. According to e-mail messages widely circulated on the Internet, an organization known as the Klingerman Foundation was mailing blue envelopes containing sponges contaminated with a fictional pathogen called the 'Klingerman virus'. According to the e-mail alert, 23 people had been infected with the virus, including 7 who died.

Viruses as Bioweapons

Advances in viral culture and virus stabilization made during the second half of the twentieth century facilitated

large-scale production of viral agents for aerosol dissemination. A report for the United Nations on chemical and biological weapons and the effects of their possible use gave estimates on the numbers of casualties produced by a hypothetical biological attack (**Table 1**). Three viruses (Rift Valley fever virus, Tick-borne encephalitis virus, and Venezuelan Equine Encephalomyelitis (VEE) virus) were evaluated in a scenario in which 50 kg of the agent was released by aircraft along a 2 km line upwind of a population center of 500 000. The viral agents produced fewer casualties and impacted a smaller area when compared with the bacterial agents used in this hypothetical model. Of note, smallpox was apparently not evaluated because it had not yet been eradicated and level of vaccine-induced immunity in the population was high.

Viral agents were part of the biological weapons arsenal of both the Soviet Union and the United States (**Table 2**). VEE virus was stockpiled by both countries as an incapacitating agent; Variola major and Marburg viruses were stockpiled as lethal agents by the Soviet Union. The Soviet Union reportedly conducted a live field test of Variola major virus on Vozrozhdeniye Island in the Aral Sea in the 1970s, in which 400 g of the virus was released into the atmosphere by explosion. Unfortunately, a laboratory technician who was collecting plankton samples from an oceanographic research vessel 15 km from the island became infected. It was reported that after returning home to Aralsk, she transmitted the infection to several people including children. All those infected died. A number of other viruses that infect humans (e.g., Ebola virus, Lassa fever virus, enterovirus 70) or livestock (e.g., foot and mouth disease virus, rinderpest, Newcastle disease virus) have also been studied for their offensive capabilities or for the development of medical and veterinary countermeasures.

Today, with the increased level of concern, a number of viruses have been cited as possible weapons for use against humans or animals (**Table 2**). The requirements for an ideal biological warfare agent include availability, ease of production, stability after production, a susceptible population, absence of specific treatment, ability to incapacitate or kill the host, appropriate particle size in aerosol so that the virus can be carried long distances by prevailing winds and inhaled deeply into the lungs of unsuspecting victims, ability to be disseminated via food or water, and the availability of a vaccine to protect certain groups. Other factors such as the economic and psychological impact of an attack on animal agriculture with a viral agent must also be considered.

Table 1 Estimates of casualties produced by hypothetical biological attack

	Downwind		
Agent	*Reach (km)*	*Dead*	*Incapacitated*
Rift Valley fever	1	400	35 000
Tick-borne encephalitis	1	9500	35 000
VEE	1	200	19 800
Francisella tularensis	>20	30 000	125 000
Bacillus anthracis	>20	95 000	125 000

Note. These estimates are based on the following scenario: release of 50 kg of agent by aircraft along a 2 km line upwind of a population center of 500 000.

Variola major is considered to be the major viral threat agent for humans. Thus, considerable effort has been expended toward preparing the public health and medical communities for the possibility that this agent will be employed by a terrorist. Variola major is considered to be an ideal terrorist weapon because it is highly transmissible by the aerosol route from infected to susceptible persons; the civilian populations of most countries contain a high proportion of susceptible persons; the disease is associated with a high morbidity and about 30% mortality; initially, the diagnosis of a disease that has not been seen for almost 30 years would be difficult; and, other than the vaccine, which may be effective in the first few days post infection, there is no proven treatment available.

Alphaviruses (**Table 2**) are also of concern because they can be produced in large amounts in inexpensive and unsophisticated systems; they are relatively stable and highly infectious for humans as aerosols, and strains are available that produce incapacitating (e.g., VEE) or lethal infections (EEE case fatality rates range from 50–75%). Furthermore, the existence of multiple serotypes of VEE and EEE viruses, as well as the inherent difficulties of inducing efficient mucosal immunity, make defensive vaccine development difficult.

The filoviruses and arenaviruses that cause hemorrhagic fever have also been considered as agents that might be used by terrorists because of their high virulence and capacity for causing fear and anxiety. The filoviruses, Ebola and Marburg, can also be highly infectious by the airborne route. Humans are generally susceptible to infection with these viruses with fatality rates greater than 80%, and infection can be transmitted between humans through direct contact with virus-containing body fluids. There are five species of arenaviruses (Lassa fever, Junin, Machupo, Guanarito, and Sabia) that can cause viral hemorrhagic fevers with a case fatality rate of about 20%. Large quantities of these viruses can be produced by propagation in cell culture. Infection occurs via the respiratory pathway suggesting that dissemination via aerosol might be used by a terrorist. Human to human transmission has also been reported with aerosol transmission the most likely route for at least some of the secondary cases. The filoviruses and arenaviruses discussed above are BSL-4

Table 2 Classification of viral agents that are considered to be of concern for bioterrorism and biowarfare and those that have been weaponized or studied for offensive or defensive purposes as part of former or current national biological weapons programs

Nucleic acid	*Family*	*Genus*	*Species*
Negative-sense single-stranded RNA	Arenaviridae	Arenaviruses	Lassa fever[a,b]

agents and diagnostic capacities for infections caused by these viruses are limited.

Impact of Biotechnology

Because the nucleic acid of many viruses, including some that are currently not threats, can be manipulated in the laboratory, the potential for genetic engineering remains a serious threat. Biotechnology, which has had a tremendous impact on the development of medicines, vaccines, and in the technologies needed to counter the threat of naturally occurring disease, can also be used to modify viruses with unintended consequences or even for the development of novel biological agents. Several examples involving viruses are presented below.

Mousepox Virus

An Australian research group was investigating virally vectored immunocontraceptive vaccines based on ectromelia virus, the causative agent of the disease termed mousepox. They created a recombinant virus, which expressed the mouse cytokine IL-4 in order to enhance the antibody-mediated response to other recombinant antigens carried on the virus vector. Instead, the ectromelia virus vector expressing IL-4 altered the host's immune response to this virus resulting in lethal infections in normally genetically

resistant mice (e.g., C57BL/6). Additionally, this virus also caused lethal infections in mice previously immunized against infection with ectromelia virus. The creation of this 'supermousepox' virus led to speculation that similar genetic engineering could be performed on Variola major leading to a biological weapon that would be effective against an immunized population.

Pandemic Influenza

The influenza pandemic of 1918–19, which followed World War I, was uniquely severe, causing an estimated 20–40 million deaths globally. This pandemic happened before the advent of viral culture and very little was known about the virus until the discovery of the polymerase chain reaction (PCR). Recently, the complete coding sequences of all eight viral RNA segments has been determined by using reverse transcription-PCR (RT-PCR) to amplify the viral RNA sequences from formalin-fixed and frozen tissue samples from individuals who died during this pandemic in an effort to shed light on both the reasons for its extraordinary virulence and evolutionary origin. More recently, researchers reconstructed the 1918 Spanish influenza pandemic virus using reverse genetics and observed that this reconstructed virus exhibited exceptional virulence in the model systems examined and that the 1918 hemaglutinin and polymerase genes were essential for optimal virulence.

Synthetic Genomes

A full-length poliovirus complementary DNA (cDNA) (*c.* 7500 bp) has been synthesized in the laboratory by assembling oligonucleotides of plus- and minus-strand polarity. The synthetic poliovirus cDNA was transcribed by RNA polymerase into viral RNA, which translated and replicated in a cytoplasmic extract of uninfected HeLa S3 cells, resulting in the *de novo* synthesis of infectious poliovirus. The publication of this research raised concerns that more complicated viruses (e.g., Variola major or Ebola) could be synthesized from scratch based on publicly available sequences, or that viruses could be created that do not exist in the wild.

Recognition, Response, and Deterrence

An effective defense requires a comprehensive approach that includes: prevention of access to viral stocks; improved means of detecting deliberately induced disease outbreaks; rapid medical recognition of specific syndromes (e.g., hemorrhagic fever syndrome); rapid laboratory identification of viruses in patient specimens; prevention of person–person transmission; reliable decontamination procedures; development of effective vaccines; and development of effective antiviral therapy.

Rapid and accurate detection of biological threat agents is the basis of an effective public health response to bioterrorism. In order to address this issue, CDC in collaboration with other partners established a national network of laboratories called the Laboratory Response Network (LRN), which was provided with the tools to accomplish this mission. Rapid assays utilizing advanced molecular and immunological technologies for detection of agents such as variola virus, as well as emerging public health threats such as SARS coronavirus and H5N1 influenza virus, were distributed to member laboratories. Equipment, training, and proficiency testing are elements of the LRN and contribute to a uniform operational plan. The importance of high-quality standardized testing for detection of these agents is exemplified by the rapid need for medical countermeasures to protect or treat civilian populations. Accurate laboratory analysis is a major element in the decision process for deployment of the Federal Government's Strategic National Stockpile (SNS) of medical countermeasures.

As part of the effort to deter biological terrorism and strengthen the law enforcement response to such an act, the US recently established a microbial forensic laboratory known as the National Bioforensics Analysis Center that operates in partnership with the Federal Bureau of Investigation. Scientists are already developing methods for the forensic investigation of incidents involving viruses.

Summary

For the terrorist, the use of a viral agent would pose a challenge due to problems associated with acquisition, cultivation, and dissemination. The target for an attack with a viral agent can range from humans to animals and plants. Therefore, agricultural targets are also a major concern. Nature has provided many challenges to combating viral diseases. Viral agents are much more prone to genetic variation and mutation, and can be manipulated or created in the laboratory to take on desired characteristics. Differentiating between natural and intentional viral disease outbreaks can be challenging. Unlike bacterial diseases, many of which are treatable, there are fewer medical countermeasures to employ when dealing with viral infections. Laboratory diagnostic methods and reagents must continuously be refined to account for genetic changes and variants. Thus, the challenge of developing bioterrorism countermeasures is significant. Fortunately, this effort contributes to combating natural disease events more effectively, which has global benefits.

Glossary

Alkaliphilic Having a requirement for an environment with a high pH.

Burst size The number of infectious virus particles released per cell.

Carrier state Persistent infection of a host cell by a virus, with the surviving host persistently carrying and continually producing virus without entering a lysogenic state.

Circular permutation A change in the sequence of the linear DNA termini that does not alter the relative sequence (e.g., circular permutation of ABCDEFGH could generate BCDEFGHA, CDEFGHAB, etc).

Concatamer Two or more DNA molecules that are linked together to form a long, linear DNA molecule.

Cured A host cell that was once a lysogen, but no longer carries viral DNA in any form.

Halophilic Having a requirement for an environment with a high salt concentration.

Headful packaging The mechanism of packaging viral DNA based on the size of the virus head, rather than the length of the viral genome.

Hyperthermophile Having a requirement for an environment with a high temperature ($>80\,^{\circ}C$).

Insertion sequences Repetitive sequences of DNA that can move from one site to another within the viral DNA.

Integrase/recombinase An enzyme which can integrate viral DNA into the genome of its host cell.

Lysogen A host cell that has been infected by a virus that remains dormant, despite the presence of viral DNA.

Lytic virus A virus that is able to infect a host, replicate, and subsequently leave the host cell by rupturing (lysing) the host cell.

Methanogenic Having the ability to produce methane.

Monovalent A virus that has a host range limited to one species.

Prophage A virus that is dormant within the host cell.

Protein-primed replication Replication of DNA via the interaction of the DNA polymerase with specific proteins, rather than DNA or RNA primers.

Temperate virus A virus that is able to infect a host, but remain dormant within the host cell.

Terminal redundancy Linear DNA with the same sequence at each end.

Transduction The transfer of host DNA from one host cell to another by a virus.

Transfection The introduction of pure viral genomic DNA into a host cell, producing viable virus.

Introduction

In comparison with the viruses infecting Bacteria and Eukarya, our understanding of viruses that infect the third domain of life, the Archaea, is still in the early stages. The first archaeal virus was accidentally discovered in 1974, 3 years before the recognition of Archaea as a separate domain. Twenty-two years later, a total of only ~35 archaeal viruses and virus-like particles (VLPs) had been reported, the vast majority of which displayed head-and-tail morphologies and possessed linear double-stranded DNA (dsDNA) genomes. By 2006, at least 63 viruses and VLPs had been described, which infect members of the two major archaeal kingdoms, Crenarchaeota, including the extremely thermophilic sulfur-metabolizers, and Euryarchaeota, including the anaerobic methanogens, the extreme halophiles, and some hyperthermophiles. All have dsDNA genomes and while the total number of archaeal viruses is still miniscule compared with the >5100 published bacteriophages, they display a wide diversity of morphologies and characteristics. This article focuses on virus representatives infecting the members of the kingdom Euryarchaeota, a group for which the diversity of known representatives has blossomed in recent years.

Early Euryarchaeal Viruses and VLPs

In the early days of euryarchaeal virus research (1974–93), the range of virus and VLP representatives of the Euryarchaeota was limited. Attempts to isolate these particles were rare and many of the published representatives were discovered accidentally, for example, as contaminants in 'pure' preparations of archaeal flagella. In hindsight, the inability to culture the environmentally dominant Archaea restricted the isolation of viruses to those that infected easily grown laboratory strains, for example, *Halobacterium* for the haloarchaea and *Methanothermobacter* and *Methanobrevibacter* for the methanogens. Except for one oblate VLP with a circular dsDNA genome observed in cultures of *Methanococcus voltae* strain A3, all representatives possessed head-and-tail morphologies with complex protein profiles and genomes of linear dsDNA, similar to the 'classical' bacteriophages of the families *Myoviridae* (head-and-tail viruses with contractile tails) and *Siphoviridae* (head-and-tail viruses with noncontractile tails).

Like their hosts, the viruses of the extremely halophilic Archaea generally required high levels of NaCl or $MgSO_4$ for stability, although halobacterium salinarum viruses Hh-1 and ΦN were relatively stable in low salt, with the latter virus retaining infectivity even after prolonged incubation in distilled water. Many of the extremely halophilic viruses (or haloviruses) were lytic, with latent periods ranging from 6 to 17 h and burst sizes between 60 and 1300 PFU/cell. These latent periods and burst sizes appeared to be regulated by external salt concentrations, a phenomenon proposed to be significant for virus replication during changing salinity conditions in the environment. Some haloviruses such as halobacterium salinarum virus ΦH were truly temperate, while others such as halobacterium salinarum virus S45 persistently infected their host cells.

The viruses of the methanogens were lytic (by definition, no infectivity could be shown for VLP A3), with latent periods ranging from 4 to 9 h and burst sizes between 6 and 20 PFU/cell. However, some controversy still exists regarding the virus–host relationship for ψM1 and relatives (see below).

In general, the characterization of the early euryarchaeal virus and VLP isolates did not progress to the molecular level and it is likely that most of the early isolates are now lost. The exceptions were ΦH, which is one of the most thoroughly studied archaeal viruses, and methanothermobacter marburgensis virus ψM1, and relatives ψM2 and ψM100 (see below). ΦH was isolated after spontaneous lysis of its host culture and was able to infect a range of *Hbt. salinarum* strains. The virion morphologically resembled members of the family *Myoviridae* and contained a linear dsDNA genome of *c.* 59 kbp, which was packaged by a headful mechanism. The genome was partially sequenced and was shown to be transcribed in early, middle, and late phases. Although the virus particles contained linear DNA, ΦH was temperate and circular viral genomes (plasmids) could be isolated from infected cells. Genomic DNA was able to be transfected into *Hbt. salinarium* and *Haloferax volcanii* cells, producing viable virus particles. This was the first demonstration of transfection in Archaea, and allowed the optimization of plasmid transformation. However, ΦH was highly unstable, due to the activity of insertion sequences and inversion of the 'L-fragment', which could act as an autonomous plasmid. For this reason, work on ΦH was discontinued in the late 1990s.

Current Euryarchaeal Viruses and VLPs

The published viruses and VLPs infecting members of the kingdom Euryarchaeota in the readily accessible literature are listed in **Table 1**. This table excludes nine uncharacterized head-and-tail viruses with *c.* 50 nm diameter heads, isolated in 1977 from the Great Salt Lake in Utah, USA, on uncharacterized *Halobacterium* isolates. The remainder of this article focuses on detailing the advances in research for euryarchaeal viruses and VLPs that have been studied since 2001.

1989. The particles resemble bacteriophages of the family *Siphoviridae*, with a head diameter of *c.* 55 nm and a tail of *c.* 210 nm × 10 nm, composed of individual segments and an enlarged terminal segment (**Figure 1**). The ψM1 virion contains a 26.8 kbp genome and three major structural proteins. The proteins appear to be encoded by two open reading frames (ORFs), designated 13 and 18, whose products are post-translationally modified to produce the three proteins. To form the larger protein, the products of the ORFs are covalently cross-linked. The smaller proteins are then formed by processing of this protein at the N- and C-termini. The product of ORF 13 is similar to proteins found in Gram-positive Bacteria and bacteriophages; for example, it shows 28% identity over 330 amino acids to prophage PBSX protein XkdG in *Bacillus subtilis*.

The linear dsDNA genome of ψM1 is terminally redundant and circularly permuted, and packaged via a headful packing mechanism. Upon passage in laboratory cultures a spontaneous ψM1 deletion mutant designated ψM2, which lacked a 0.7 kbp segment (DR1), was found to become dominant. The 26.1 kbp ψM2 genome (AF065411) (**Figure 2**) and the DR1 ψM1 segment (AF065412) were sequenced. The ψM2 genome has a guanine–cytosine (GC) content of 46.3% and encodes 31 ORFs, seven of which have been assigned putative functions, again similar to those in Gram-positive Bacteria and bacteriophages. This suggests some gene exchange between bacterial and archaeal viruses, or a common ancestor of the bacterial and archaeal viruses. DR1 encodes ORF A, a duplication of ψM2 ORF 27. Although this element affects the stability of ψM1, the insertion and deletion of DR1 does not appear to interrupt any downstream ORFs.

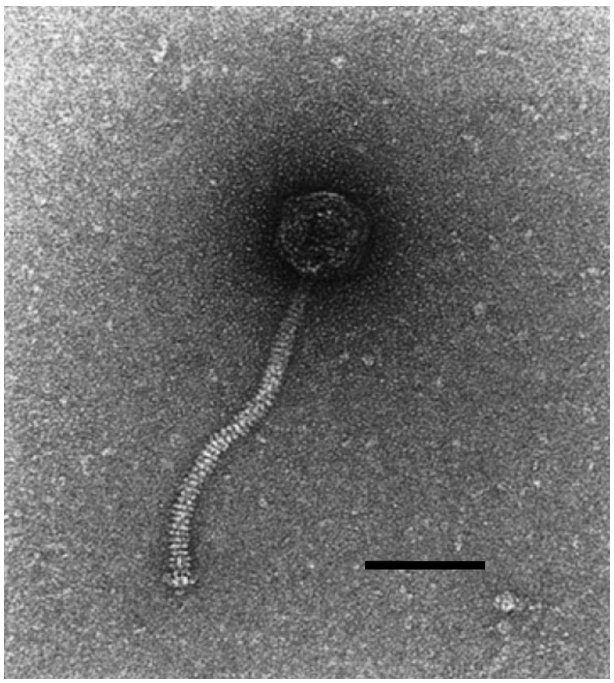

Figure 1 Electron micrograph of ψM1, negatively stained with uranyl acetate. Scale = 70 nm. Adapted from *Archives of Microbiology*, 152, 1989, p. 106, Characterization of ψM1, a virulent phage of *Methanobacterium thermoautotrophicum* Marburg, Meile L, Jenal U, Studer D, Jordan M, and Leisinger T, figure 1, © Springer-Verlag 1989, with kind permission from Springer Science and Business Media.

Under laboratory conditions, ψM1 is a lytic virus, with no evidence of lysogen formation. The virus produces a pseudomurein endoisopeptidase, a lytic enzyme that cleaves host pseudomurein, encoded by *peiP* (ORF 28). Unexpectedly, ORF 29 encodes a putative site-specific integrase/recombinase, suggesting that ψM1 and ψM2 are actually temperate. This theory is supported by the absence of a viral DNA polymerase, which is usually found in lytic viruses, and the capacity of ψM1 particles to mediate transduction of resistance and biosynthesis markers, an ability as yet unobserved in other archaeal viruses. In addition, ψM1-resistant cultures of *Methanothermobacter wolfeii* spontaneously lyse and carry a chromosomal prophage, known as ψM100, which is homologous to ψM1 and ψM2. ψM100 appears to be a defective virus, as no VLPs are observed in autolysates but pseudomurein endoisopeptidase PeiW, encoded by ψM100 ORF 28, is present. The 28.8 kbp ψM100 sequence (AF301375) (**Figure 2**) has a GC content of 45.4%. It contains a 2.8 kbp fragment, IRFa, which has a GC content of 33.4% and apparently originates from a source not homologous to ψM1 and ψM2. The remaining 26.0 kbp of the ψM100 genome is 70.8% identical to ψM2. The lytic/temperate relationship between ψM1-like viruses and *M. marburgensis* remains unresolved.

Viruses of the Extremely Halophilic Archaea

Head-and-Tail Viruses HF1 and HF2

In 1993, a deliberate search for haloviruses infecting a wider range of haloarchaea resulted in the isolation of HF1 and HF2 from Cheetham Saltworks in Victoria, Australia. Both viruses are lytic, but can enter unstable carrier states in laboratory cultures. They have mutually exclusive host ranges, HF1 infecting a wide range of hosts from the genera *Haloarcula*, *Halobacterium*, and *Haloferax*, while HF2 strictly infects *Halorubrum* species. HF2 is sensitive to chloroform exposure, but HF1 is relatively insensitive to this solvent. In aspects other than host range and chloroform sensitivity, HF1 and HF2 are very similar. Their particles have identical morphologies, resembling bacteriophages of the family *Myoviridae*, with heads of *c.* 58 nm in diameter and tails of *c.* 94 nm in length (**Figure 3**). The structural proteins of HF1 and HF2 are very similar, with four major and several minor proteins. They also share similarly sized genomes of linear dsDNA.

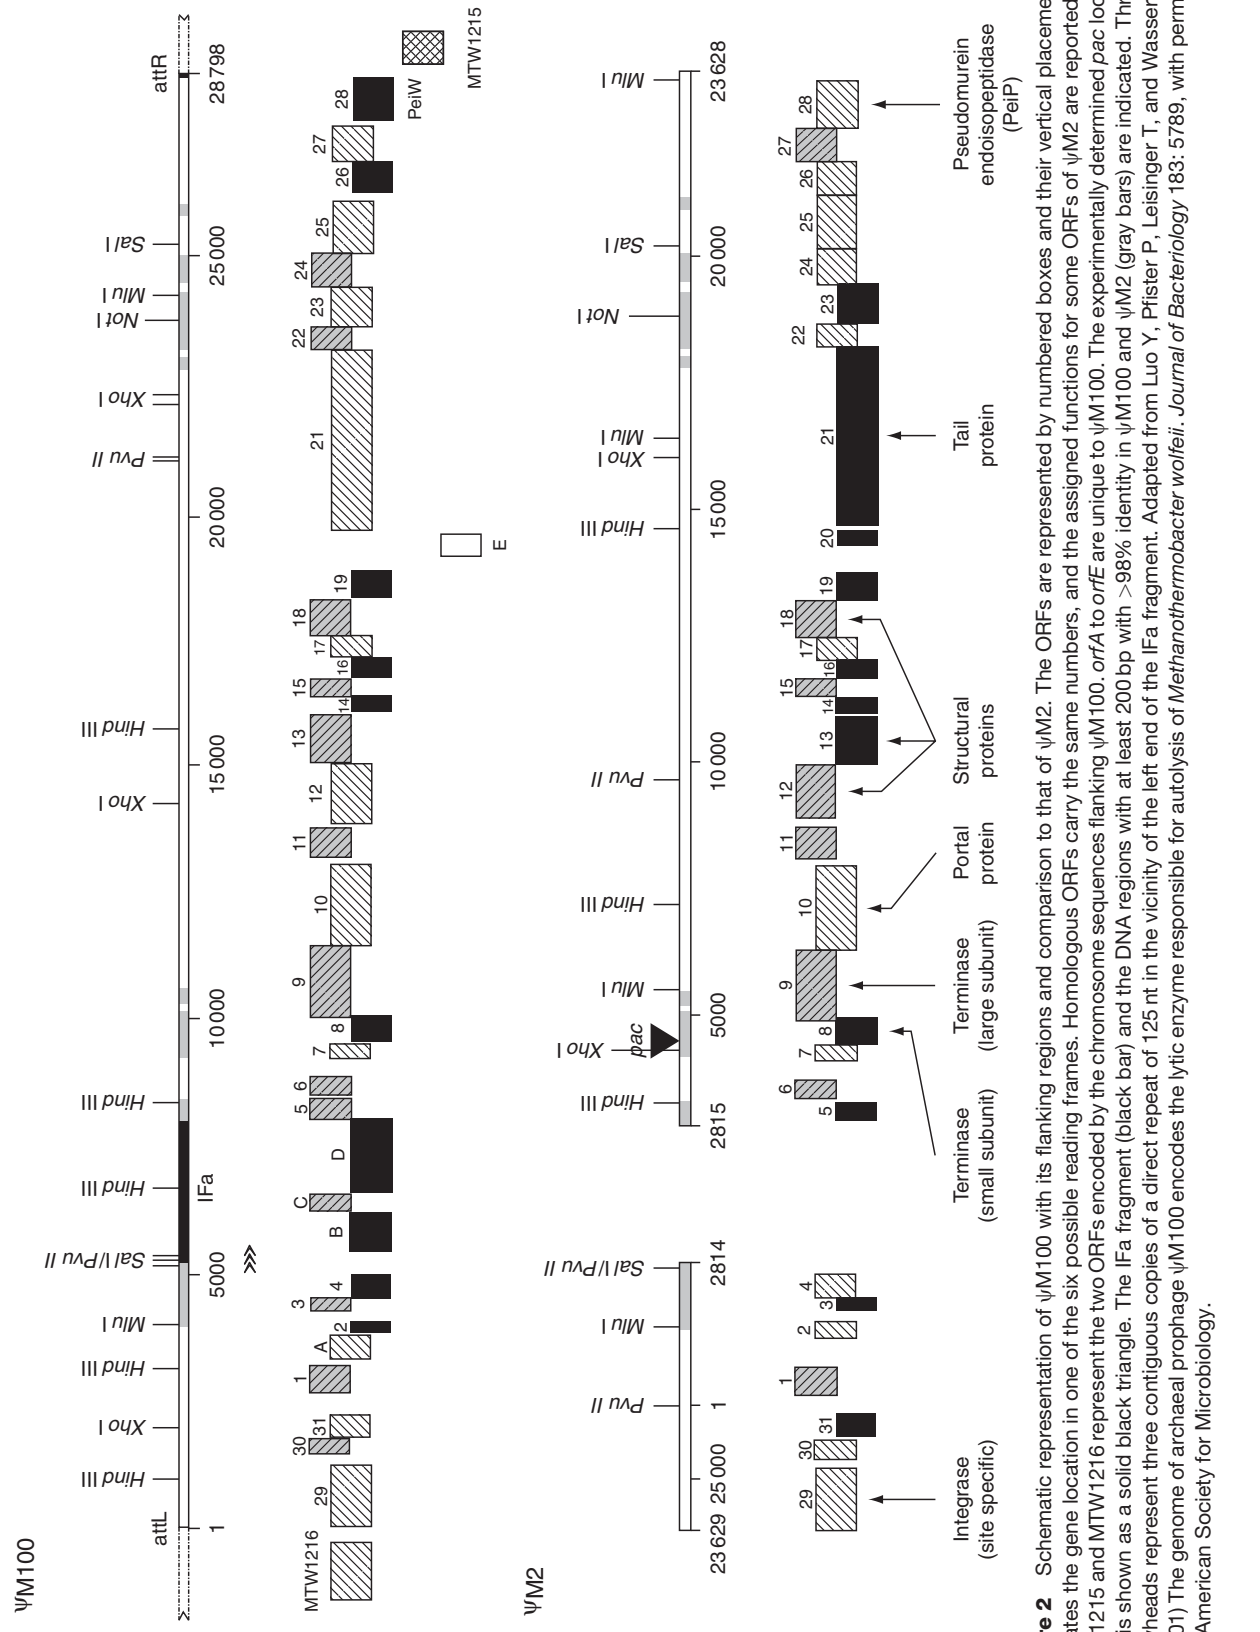

Figure 2 Schematic representation of ψM100 with its flanking regions and comparison to that of ψM2. The ORFs are represented by numbered boxes and their vertical placement indicates the gene location in one of the six possible reading frames. Homologous ORFs carry the same numbers, and the assigned functions for some ORFs of ψM2 are reported. MTW1215 and MTW1216 represent the two ORFs encoded by the chromosome sequences flanking ψM100. *orfA* to *orfE* are unique to ψM100. The experimentally determined *pac* locus for ψM2 is shown as a solid black triangle. The IFa fragment (black bar) and the DNA regions with at least 200 bp with >98% identity in ψM100 and ψM2 (gray bars) are indicated. Three arrowheads represent three contiguous copies of a direct repeat of 125 nt in the vicinity of the left end of the IFa fragment. Adapted from Luo Y, Pfister P, Leisinger T, and Wasserfallen A (2001) The genome of archaeal prophage ψM100 encodes the lytic enzyme responsible for autolysis of *Methanothermobacter wolfeii*. *Journal of Bacteriology* 183: 5789, with permission from American Society for Microbiology.

The genome of HF2 (AF222060) replicates via concatamer formation. It is 77.7 kbp in length (**Figure 4**), has a GC content of 55.8%, and contains 121 closely spaced ORFs. Approximately 12% of ORFs show similarity to known sequences. The HF2 ORFs are transcribed as operons, with distinct early, middle, and late transcripts. The ORFs are likely to be strategically organized into three groups: (1) genes involved in establishing infection; (2) genes involved in DNA synthesis, modification, and replication; (3) and genes involved in virus assembly and release. There are long intergenic repeats throughout the genome, which appear to be linked to transcription regulation. The genomic arrangement suggests that such viruses mediate genetic exchange across a range of hosts, resulting in mosaic virus genomes (see below).

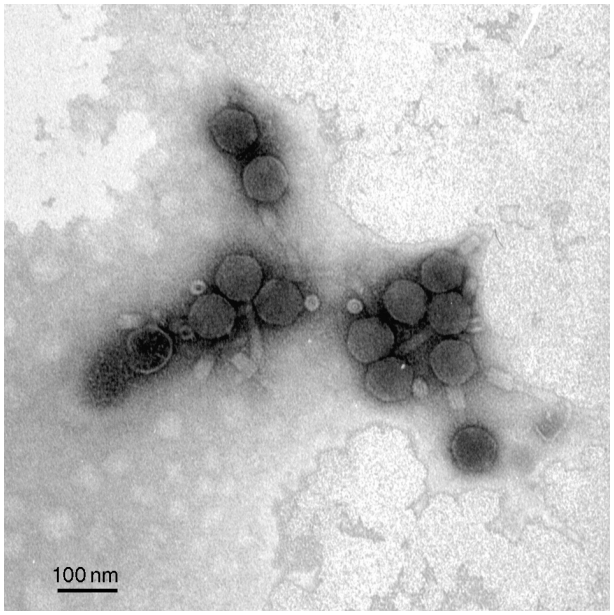

Figure 3 Electron micrograph of HF2, negatively stained with uranyl acetate.

The HF1 genome (AY190604) is 75.9 kbp in length (**Figure 4**), has a GC content of 55.8%, and encodes 117 ORFs, of which 13% show similarity to known sequences (excluding those of HF2). The first 48 kbp of the HF1 genome is identical to that of HF2, apart from one silent base change, and the remaining sequence is 87% identical. In the latter region, HF2 contains two unique ORFs, two pairs of ORFs that are joined in HF1, and several ORFs with less than 70% amino acid identity to those in HF1. Divergence in this region of the genome probably explains the wide differences in viral host range and chloroform sensitivities of the two viruses. The path of sequence divergence also indicates that a recent recombination event exchanged the end of one virus for that of a third, unknown but related, virus.

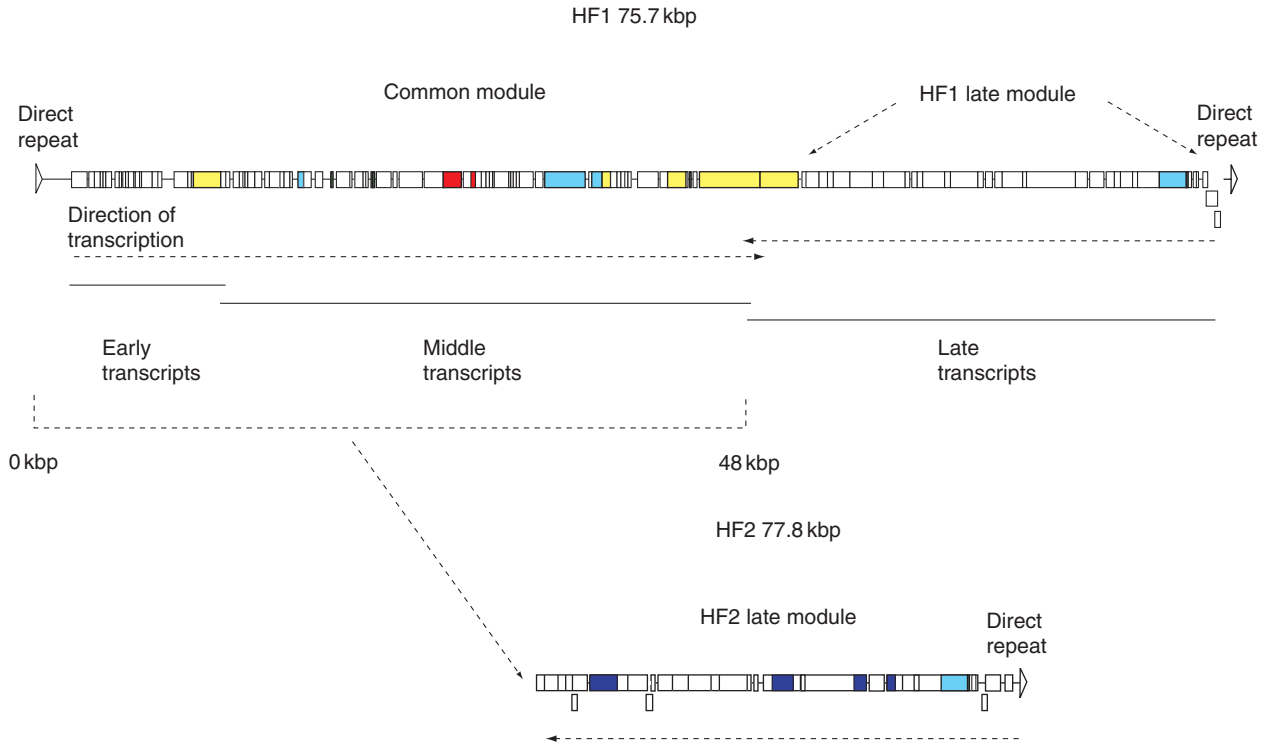

Figure 4 Closely related haloviruses HF1 (75.898 kbp) and HF2 (77.670 kbp) have genomes that are identical from 0 to 48 kbp, after which there is significantly lower homology. Direction of transcription is indicated below the genes in the diagram, as is the pattern of gene expression. Genes are drawn to scale. Genes highlighted in red are involved in transcription; dark blue – virion structure; yellow–nucleic acid modification; light blue – replication and repair.

The Haloalkaliphilic Virus, ΦCh1

Although most extremely halophilic Archaea live at a neutral pH, there is a group that is not only extremely halophilic, but is also alkaliphilic. In 1997, a haloalkaliphilic virus, ΦCh1, was isolated after spontaneous lysis of a culture of the haloalkaliphilic archaeon *Natrialba magadii*. ΦCh1 is monovalent, producing plaques on lawns of ΦCh1-cured *Nab. magadii* cells. The virus is also temperate, with lysogens containing genomic ΦCh1 DNA integrated into the *Nab. magadii* chromosome. Virus integration is potentially mediated by putative site-specific recombinases, Int1 and Int2, encoded by ORFs 35 (*int1*, which has been shown to mediate inversion and excision reactions, resulting in small, circular molecules) and 45 (*int2*).

ΦCh1 particles resemble the family *Myoviridae*, with a head of *c.* 70 nm in diameter and a contractile tail *c.* 130 nm × 20 nm (**Figure 5**). The ΦCh1 virion contains at least nine structural proteins, designated A to I in decreasing size order. Proteins A and H are encoded by ORF 19 and protein E is encoded by ORF 11 (gene *E*). Gene *E* is transcribed late in cell infection and protein E is found to be associated with the host membrane, suggesting a role in DNA packaging or assembly of coat proteins during viral exit.

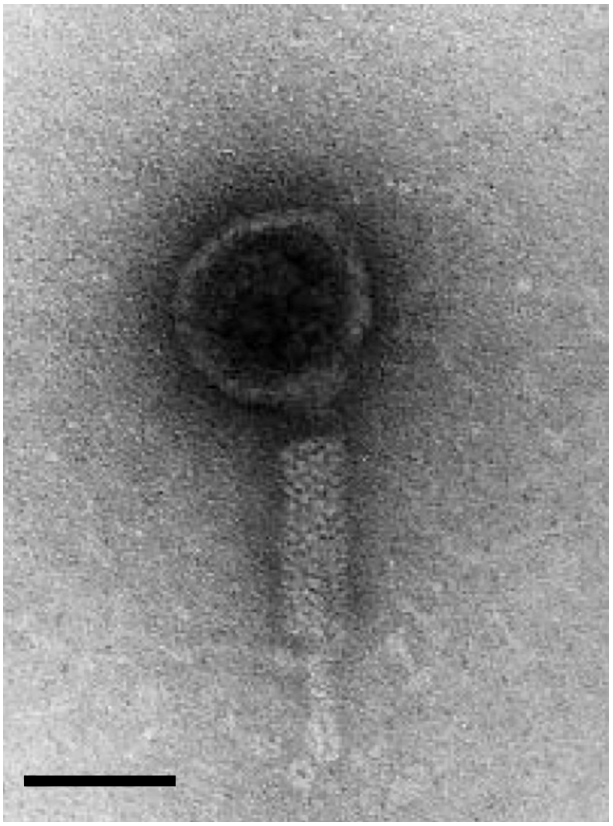

Figure 5 Electron micrograph of ΦCh1, negatively stained with phosphotungstate. A contracted tail and the anchor structure between head and tail are visible. Scale = 50 nm. Adapted from Witte A, Baranyi U, Klein R, *et al*. (1997) Characterization of *Natronobacterium magadii* phage ΦCh1, a unique archaeal phage containing DNA and RNA. *Molecular Microbiology* 23: 605, with permission from Blackwell Science Ltd.

ΦCh1 virus particles contain both linear dsDNA and host-derived RNA species. Genomic ΦCh1 DNA is modified at adenine residues within various sequences, including 5′-GATC-3′. Although DNA methylation is a common viral mechanism for avoiding host-mediated restriction, it was unexpected in ΦCh1, as *Nab. magadii* does not have methylated DNA. An N^6-adenine methyltransferase, encoded by ORF 94 of ΦCh1, is transcribed and expressed late in cell infection. These factors suggest that ΦCh1 may infect other hosts.

The ΦCh1 genome has a circular replicative form and is circularly permuted and terminally redundant, suggesting a headful packing mechanism. The 58.5 kbp genome (AF440695) has a GC content of 61.9% and is predicted to contain 98 ORFs (**Figure 6**). In a similar manner to head-and-tail bacteriophages, the ORFs appear to be organized into three transcriptional units encoding (1) structural and morphogenesis proteins; (2) replication, stabilization, and gene regulation proteins; and (3) proteins of mostly unknown functions. Around half of the ORFs show similarity to sequences in the databases, although most of these are proteins of unknown function. The genome sequence of ΦCh1 shows strong similarity to the incomplete genome of ΦH, which is surprising given that the two viruses were isolated from distinctly different environments and hosts. This unexpected relationship between supposedly diverse viruses suggests that similar viruses may be widely distributed throughout various hypersaline environments across the planet.

His1 and His2: Spindle-Shaped Haloviruses of the Genus *Salterprovirus*

From 1974 to 1998, all of the viruses described for the kingdom Euryarchaeota were of head-and-tail morphology. Nevertheless, in waters such as the Dead Sea, the most abundant VLPs observed by direct electron microscopy were spindle shaped. In a study of a Spanish saltern, spindle-shaped VLPs were found to increase in abundance with increasing salinity. In 1998, a spindle-shaped halovirus, His1, was reported. Isolated from the Avalon saltern in Victoria, Australia, on a lawn of *Haloarcula hispanica*, the His1 virion is *c.* 74 nm × 44 nm, with a short 7 nm tail (**Figure 7(a)**). His1 resembles crenarchaeal virus SSV1 and due to the morphological similarities and comparable genome sizes of these two viruses, His1 was initially, and mistakenly, placed in the *Fuselloviridae* family of archaeal viruses (type species, SSV1).

In 2006, a second spindle-shaped virus named His2 was described. It was isolated from the Pink Lakes in Victoria, Australia, and also plaques on *Har. hispanica*. By negative-stain electron microscopy, His2 particles are

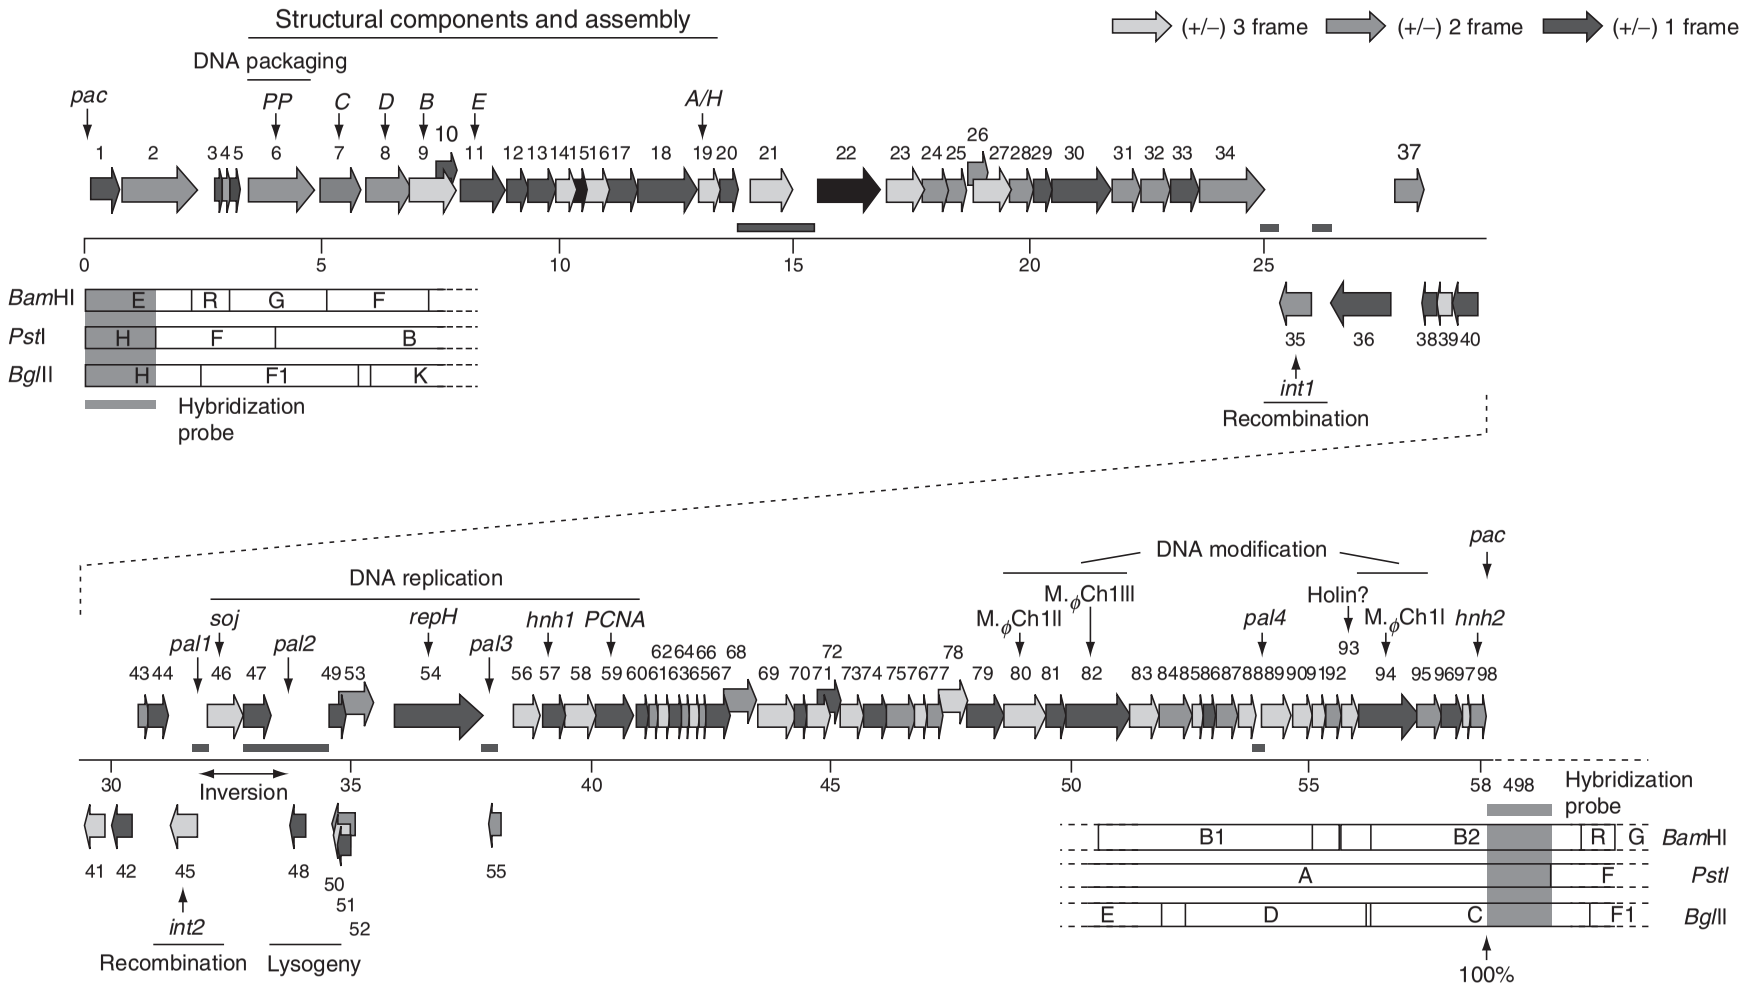

Figure 6 Linear representation of the 58 498 bp ΦCh1 genome, starting at the *pac* site. ORFs are represented by arrows and numbered. Putative and verified functions of predicted gene products are indicated. The shades of the arrows indicate the frames of the ORFs: light gray, third reading frame; mid-gray, second reading frame; and dark gray, first reading frame for both orientations. A partial restriction map showing the region embedding the *pac* site and the fragments that are created during the cut at *pac* is given beneath the genome map. Both maps are correlated with each other. The binding region for the hybridization probe that was used to map the *pac* site is shaded. Low G+C regions are indicated by black bars, and the segment that is inverted in pΦHL with respect to ΦCh1 is indicated by an arrow. The putative binding sites for site-specific recombinases, *pal1* to *pal4*, are also indicated. Adapted from Klein R, Baranyi U, Rössler N, Greineder B, Scholz H, and Witte A (2002) *Natrialba magadii* virus ΦCh1: First complete nucleotide sequence and functional organization of a virus infecting a haloalkaliphilic archaeon. *Molecular Microbiology* 45: 852, with permission from Blackwell Science Ltd.

more flexible than His1 particles, with the virions being *c.* 67 nm × 44 nm, with a short tail (**Figure 7(b)**). The His2 virion contains at least four structural proteins, designated viral protein (VP) 1 (62 kDa) to VP 4 (21 kDa). To date, the ORFs encoding VPs 2 and 3 have not been determined. VP 1 is encoded by ORF 29 and predicted to be exported to the cell surface and glycosylated. ORF 29, and the downstream ORFs 30, 31, and 33, have closely similar sequences in at least four species of extremely halophilic Archaea, although the segments of similarity do not appear to be part of provirus genomes. The functions of these archaeal homologs have not yet been determined.

Although both monovalent haloviruses are virulent, they appear to enter a carrier state and have the capacity to exit cells without causing cell lysis. His1 and His2 are relatively stable in the pH range 3–9; however, His1 is more resistant than His2 to exposure to both increased temperature and lowered ionic environments. Both His1 and His2 are sensitive to chloroform and have low buoyant densities and flexible virus particles. These factors suggest that the virions contain lipids.

The genomes of haloviruses His1 (AF191796) and His2 (AF191797) are linear dsDNA of 14.5 and 16.1 kbp, respectively (**Figure 8**). The genomes have a GC content of *c.* 40%, about 23% lower than *Har. hispanica*, suggesting that the haloviruses are not well equipped to replicate in *Haloarcula*. Moreover, no tRNA genes have been detected in the genomes of these viruses.

The His1 and His2 genomes each contain 35 ORFs and show almost no sequence similarity to one another or to known sequences. The notable exceptions are the putative DNA polymerases of the two viruses, which are weakly similar to one another at the nucleotide level and show 42% identity at the protein level. The DNA polymerases appear to be members of family B DNA polymerases that use the protein-priming mechanism. The His1 and His2 genomes have inverted terminal repeat (ITR) sequences at each end (105 and 525 nt, respectively), and the 5′ end of each is linked to a terminal protein (TP), which is essential for DNA replication. These characteristics are typical of systems that replicate DNA via protein priming.

At the molecular level, His1 and His2 are distantly related to one another; however, they do not appear to be related to fuselloviruses at all, with distinctly different genome structures, replication strategies, virus–host relationships, and genome sequences. Consequently, haloviruses His1 and His2 have been placed in an independent virus genus, *Salterprovirus*.

Spherical Halovirus SH1

In addition to the spindle-shaped and head-and-tail VLPs observed in hypersaline waters such as the Dead Sea, isometric particles were also present in high numbers. These could have been classical head-and-tail VLPs, which had lost their tails through the negative-stain treatment, which tends to disrupt halophilic virus particles. However, in 2003, a spherical halovirus named SH1 that resembled these isometric particles was first noted. It was isolated from Serpentine Lake, Rottnest Island, Western Australia, on *Har. hispanica*. The SH1 virion is *c.* 70 nm in diameter and displays an outer capsid layer with a compact core particle of *c.* 50 nm in diameter (**Figure 9**). Morphologically, it resembles viruses such as the bacteriophage PRD1, human adenovirus, and archaeal virus STIV, which all share common architecture.

SH1 is virulent, infecting both *Har. hispanica* and an uncharacterized isolate of the genus *Halorubrum*. The virion is stable to exposure to temperatures of 50 °C and in a pH range of 6–9, but is sensitive to exposure to both chloroform and lowered ionic environments. SH1 particles contain a lipid layer and 15 structural proteins,

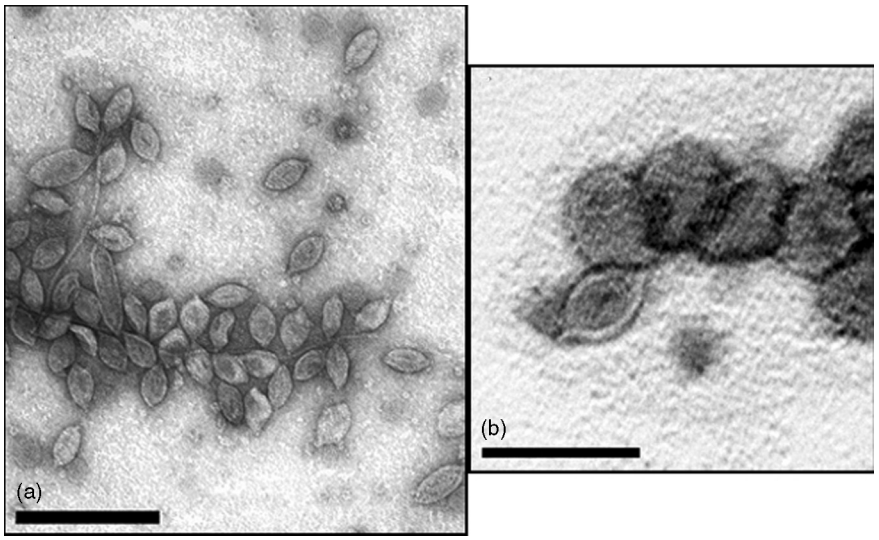

Figure 7 Electron micrograph of (a) His1 and (b) His2, negatively stained with uranyl acetate. Scale = 200 nm (a); 100 nm (b).

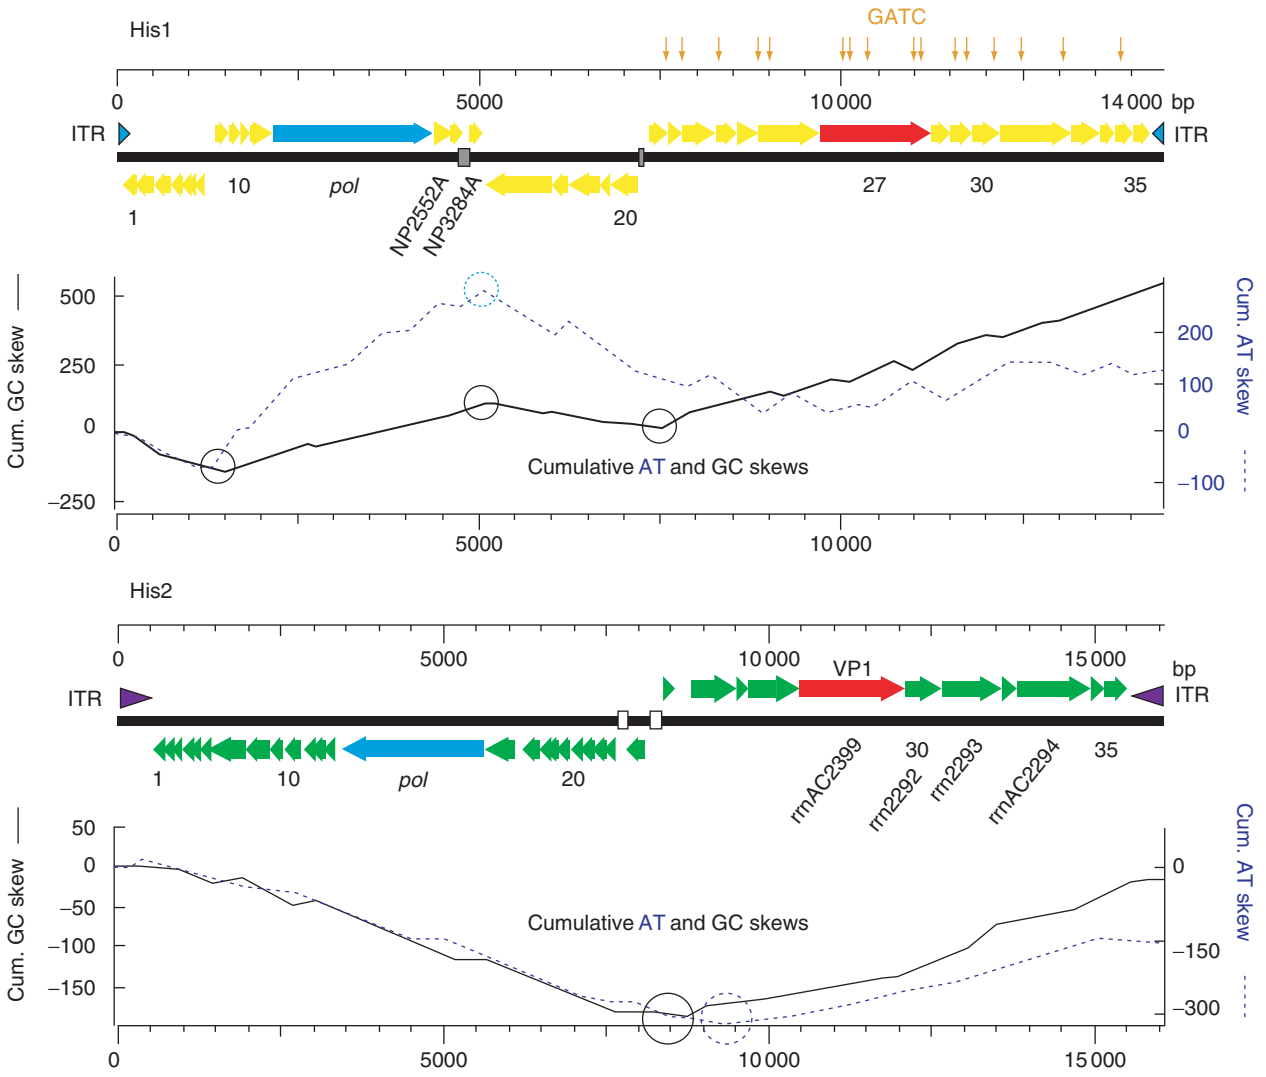

Figure 8 Diagram of the His1 and His2 genomes. The major features are shown, including the predicted ORFs (yellow and green arrows), putative DNA polymerases (blue arrows), VP1 and its His1 homolog (red arrows), terminal inverted repeat sequences (purple arrowheads), and regions of nucleotide sequence repeats (gray boxes). Scale bars, in bp, are shown above each genome diagram. ORFs are numbered (left to right), and some have been named (*pol*, DNA polymerase; VP1, major capsid protein) or the accession numbers of closely related sequences given. The template strand for each ORF is indicated by the direction of arrows and their position above or below the black line. The vertical arrows about the His1 genome scale bar show positions of the sequence GATC. Plots of cumulative GC skew (solid black line) and AT skew (dashed blue line) are shown below each genome diagram, with inflection points indicated by circles. Adapted from Bath C, Cukalac T, Porter K, and Dyall-Smith ML (2006) His1 and His2 are distantly related, spindle-shaped haloviruses belonging to the novel virus group, *Salterprovirus*, *Virology* 350: 233, with permission from Elsevier.

designated VP 1 to VP 15 in decreasing size order. Details on the locations and possible functions of the SH1 virion proteins are available.

The genome of SH1 (AY950802) is linear dsDNA of 30.9 kbp (**Figure 10**), with a GC content of 68.4%. The viral genome contains 56 ORFs, which show very little sequence similarity to known sequences. It contains 309 bp ITRs. The molecular features of SH1 indicate that it is a member of a novel virus group. Based on the evidence from electron microscopy surveys, haloviruses similar to SH1 are likely to be widespread and dominant members of hypersaline systems.

PAV1, A VLP of the Hyperthermophilic Order Thermococcales

No virus has ever been reported to infect the hyperthermophilic Euryarchaeota. However, two major groups of VLPs, rod-shaped particles and spindle-shaped particles, have been observed in enrichment cultures of samples obtained from deep-sea hydrothermal vents. In 2003, such spindle-shaped VLPs were discovered in supernatant of a '*Pyrococcus abysii*' culture and were designated '*P. abysii*' virus 1 (PAV1). PAV1 is continuously released, but does not cause lysis of host cells and cannot be

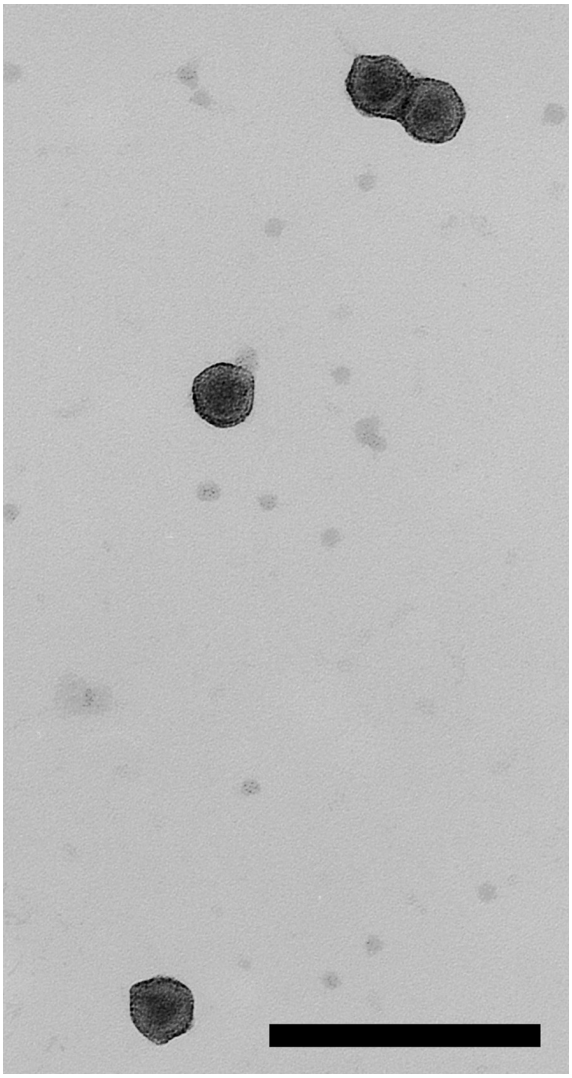

Figure 9 Electron micrograph of SH1, stained with uranyl acetate. Scale = 200 nm.

induced to infectivity using ultraviolet or γ irradiation, mitomycin C, or heat or pressure shock. No viral genomes integrated into the host chromosome have been detected.

PAV1 particles are flexible and similar in appearance to both the fuselloviruses and the salterproviruses, being *c.* 120 nm × 80 nm, with a tail of *c.* 15 nm and tail fibers (**Figure 11**). The virion is composed of at least three structural proteins, of *c.* 6, 13, and 36 kDa. PAV1 is sensitive to exposure to chloroform, Triton X-100, proteinase K, and sodium dodecyl sulfate. Combined with its low buoyant density and flexible particles, this suggests that the particles contain lipid.

The genome of PAV1 is circular dsDNA of 17.5 kbp. It contains 24 putative ORFs, which show no similarity to sequences in the databases. A detailed description of the PAV1 genome should be published soon.

Conclusion

At first glance, it may appear that the virus representatives of the kingdom Euryarchaeota resemble the more thoroughly studied bacterial and eukaryal viruses, or the viruses of the kingdom Crenarchaeota. However, on a molecular level, the euryarchaeal viruses are clearly distinct and radically different from any other known viruses. Many of the representatives, such as PAV1 and SH1, show almost no similarity to any sequences in the databases and even the head-and-tail representatives, which appear to resemble the 'classical' bacteriophages in both morphology and genome structure, encode many previously unobserved genes.

Fortunately, it appears that we are now in a good position to culture euryarchaeal viruses. Whether all the dominant morphological forms of euryarchaeal viruses have been isolated is still uncertain; however, the current

cultivation techniques appear to have isolated all of the dominant morphological forms of haloviruses (head-and-tail, spindle shaped, and spherical) that have been observed in hypersaline waters. The current representatives suggest that there may be relatively few dominant virus families infecting the kingdom Euryarchaeota, and that these virus families may be widespread. This view may change radically when the metagenomic studies of archaeal environments, such as those performed by the Venter Institute program, begin to bear fruit. In any case, the major goal now is to develop genetic systems to analyze the viruses already isolated, in order to explore and understand their genetic properties, ecological significance, and evolutionary impact.

Visna-Maedi Viruses

B A Blacklaws, University of Cambridge, Cambridge, UK

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Dyspnea Shortness of breath.
Endocytosis Where a particle is enveloped by the cell membrane and internalized into a vacuole, an endosome.
Germinal center Area where B cells undergo proliferation after encountering their specific antigen with helper T lymphocytes.
Glomerulonephritis Inflammation of the glomeruli.
Hyperplasia Increase in the number of cells.

Leukoencephalitis Inflammation of the brain caused by leukocytes.
Lymphoid follicle Organized lymphocyte clusters.
Pneumonitis Inflammation of the lung.

Introduction

Visna-maedi virus (VMV) is a retrovirus in the genus *Lentivirus*. Other lentiviruses are human (HIV), simian (SIV), feline (FIV), and bovine (BIV) immunodeficiency viruses, caprine arthritis encephalitis virus (CAEV), and equine infectious anemia virus (EIAV). VMV causes a persistent infection of sheep leading to pneumonitis, demyelinating leukoencephalitis, mastitis, and arthritis, eventually killing the host. VMV originally came to prominence during an epidemic of lung and a separate wasting disease in sheep in Iceland from the 1930s to the 1950s. It was isolated from cases of interstitial pneumonitis (*maedi* = shortness of breath in Icelandic) and demyelinating leukoencephalomyelitis (causes *visna* = wasting in Icelandic) and was the first lentivirus isolated in 1957. Study of the Icelandic epidemic, with scrapie and ovine pulmonary adenomatosis (caused by another retrovirus, Jaagsiekte sheep retrovirus), allowed Björn Sigurdsson to introduce the concept of slow viral infections in 1954. These infections are typified by long incubation periods with pathology developing slowly and progressively, eventually leading to death of the host. The derivation of the genus name, *lenti* (Latin for slow), comes from this.

Clinical lung disease typical of maedi, and in many cases now known to be caused by VMV viruses, has been described since the early 1900s in other countries. Maedi is therefore also known as ovine progressive pneumonia or Montana sheep disease (USA), Graaf Reinet disease (South Africa), zwoegerziekte (the Netherlands), and la bouhite (France). VMV (and/or CAEV) is present in most countries worldwide apart from Iceland (eradicated during the 1940s and the 1950s), Australia, and New Zealand. Where infections are present, economic losses due to loss of milk production, failure to thrive, early culling, and death of animals are seen.

The major target cells for VMV are macrophages and dendritic cells. These are also common target cells for all the other lentiviruses. Aspects of lentivirus infection such as early infection and sites of persistence in accessory cells of the immune system may therefore be studied with VMV without the complication of lymphocyte infection.

Small Ruminant Lentiviruses

Historically, when a lentivirus was isolated from sheep, it was classified as VMV and from goats as CAEV. Although it was known that experimentally VMV could infect goats and CAEV infect sheep, it was not until recently that the natural interspecies transmission of the viruses was shown by molecular epidemiology. Sequencing data from geographically distant countries and from incidences of interspecies transmission into previously uninfected populations shows that VMV and CAEV are able to infect either species as well as other wild small ruminant species. The viruses have therefore now been grouped together as the small ruminant lentiviruses (SRLVs) although the terms VMV and CAEV are also in common use. This article focuses on studies using 'classical' VMV strains in sheep but also draws on data from CAEV and goats.

Visna-Maedi Virus

Virion and Genome

The virion is enveloped with a spherical or coffin-shaped core like other lentiviruses. The virion packages a diploid RNA genome of 9189–9256 bp. Several strains and molecular clones have been fully sequenced. It is a complex retrovirus with three structural genes, *gag*, *pol*, and *env*, and three auxilliary genes, *vif*, *tat* (or *vpr*), and *rev* (**Figure 1**). The functions of the different gene products have been deduced by direct study of VMV and CAEV and also by comparison to HIV and other lentiviruses (**Table 1**).

Replication Cycle

Replication of the virus occurs in a manner similar to that of other retroviruses. Virus binds directly to the cellular receptor or via Fc receptors if coated in antibody. The virion core is released into the cytoplasm by fusion of the envelope with the plasma membrane or, if the particle has been taken up by endocytosis, with the endosomal membrane. The RNA genome is reverse-transcribed to a double-stranded DNA (dsDNA) intermediate (provirus). The process of DNA replication duplicates the RNA termini forming the long terminal repeats (LTRs) of the provirus which contain the virus promoter, mRNA start site, and polyadenylation signals. The provirus integrates into the host cell genome with no apparent preferred site for integration. It is this integrated provirus that serves as template for viral mRNA and genome production. VMV has a complex mRNA expression pattern. *In vitro*, during productive replication of fibroblast cells, there is early synthesis and transport of *tat*/*vpr* and *rev* doubly spliced mRNA to the cytoplasm. Once REV is expressed, late synthesis and transport of *gag*, *pol*, *env*, and *vif* single or unspliced mRNAs or genomic RNA are mediated. This allows expression of the viral structural proteins, virion assembly (by budding through the plasma membrane or into vacuoles), and thus productive replication.

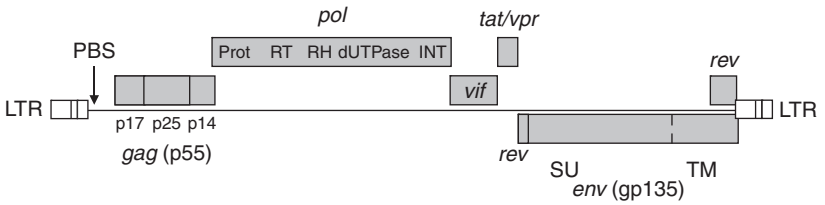

Figure 1 Proviral map of VMV. The provirus structure of VMV is shown with the position of open reading frames indicated. The proviral long terminal repeats (LTRs) contain the U3, R, and U5 regions (in this order) made during reverse transcription. The viral RNA genome contains R/U5 and U3/R at the 5′ and 3′ termini, respectively, where R is a short direct repeat. The primer binding site (PBS) for initiation of reverse transcription is indicated (binds tRNA lysine). The open reading frames are *gag*, *pol*, *vif*, *tat/vpr*, *env*, and *rev*, which contains two exons.

Table 1 Gene products of VMV

ORF	*mRNA*	*Products*	*Function*
gag	Full-length unspliced	Precursor Gag p55 cleaved to:	Major core proteins of virion
		Matrix p17	
		Capsid p25	
		Nucleoprotein p14	
pol	Full-length unspliced	Precursor Gag/Pol polyprotein made by ribosomal frameshift, cleaved to:	
		Protease	Aspartic protease cleaves Gag and Pol
		Reverse transcriptase	Synthesizes proviral cDNA
		RNase H	Degrades genomic RNA to allow second-strand cDNA synthesis
		dUTPase	Reduces dUTP incorporation and so A-to-G mutation in second-strand synthesis. Mutants attenuated *in vitro* and *in vivo*
		Integrase	Integrates provirus into host genome
env	Singly spliced	Precursor Env gp135 cleaved to:	
		Surface subunit, SU gp110	Binds to cellular receptor
		Transmembrane subunit, TM gp41	Fuses viral envelope to cellular membrane (plasma or endosomal) to release virion core into cytoplasm
vif	Singly spliced	VIF	Assumed to be like HIV-1 VIF: inhibits incorporation of cytidine deaminases into virion and so stops new cDNA degradation or G-to-A mutations. Mutants attenuated *in vitro* and *in vivo*
tat/vpr	Doubly spliced	TAT/VPR	Historically called TAT but little evidence to support TAT function, more similar to VPR: LTR has no TAR element, high promoter activity without TAT, and TAT increases promoter activity by two- to threefold; cellular location nuclear; not secreted; packaged in virion; arrests cells in G2 phase of cell cycle. Mutants viable *in vivo* and *in vitro*
rev	Doubly spliced	REV	Interacts with rev-responsive element (RRE) in *env* coding region to allow export of unspliced and singly spliced mRNA species from the nucleus

Target Cells

Monocyte/macrophages and dendritic cells are the major target cell type infected *in vivo* although other cell types have also been shown to either harbor viral nucleic acid or express viral protein, for example, lung, gut, and mammary gland epithelial cells. The frequency of infected cells *in vivo* is very low with often less than 1% of the macrophage population being infected. There is no productive infection of lymphocytes unlike the primate lentiviruses. The range of cells that VMV infect *in vitro* is wider than macrophages with fibroblasts, an important resource for growing virus in the laboratory, and epithelial, endothelial, and smooth muscle cells all reported to replicate virus.

Replication in the monocyte/macrophage lineage is tightly linked to the maturation stage of the macrophage. Three replication states have been suggested: latent,

restricted, and productive. Latent is where cells contain provirus but do not express viral products. In productive infection *in vitro* and *in vivo*, cells express approximately 5000 copies of viral RNA per cell, contain viral proteins, and produce virions. *In vivo* however, most infected cells express low quantities (approximately 5–200 copies) of viral RNA but no protein. This is called restricted replication and is seen in immature macrophages, for example, blood monocytes. It is only when macrophages mature in tissues that productive viral replication is found. Thus macrophages have been called 'Trojan horses' in SRLV infection in that they silently deliver the virus to tissues where virus replication can occur.

The cellular receptors for SRLV have not been identified although VMV strains K1514 and EV1 use a receptor(s) widely expressed on different cells and species. For K1514 this has been mapped to sheep chromosome 3p and the syntenic region of human chromosome 2 (2p25 > q13), and for EV1 to mouse chromosomes 2 and/or 4. If a one-component receptor is assumed, this excludes ovine major histocompatibility complex (MHC) class II (previously identified as a possible receptor by Env binding) and many of the cellular proteins used as co-receptors by other lentiviruses, for example, CXCR4 and CCR5. Studies using viral binding to cellular blots have identified possible candidate receptor proteins that have not yet been fully identified although a membrane proteoglycan is implicated. CAEV strains 63 or Cork may use a receptor which is much more restricted in expression in different species and although it has not been identified, is known, from interference and inhibition assays, to be different from the receptor for VMV strain K1514.

The cellular tropism of VMV is also affected by the ability of the virus to express the provirus. Different promoter activities are the consequence of LTR sequence and its ability to bind different transcription factors. Unlike the primate lentiviruses, SRLV LTRs have no NF-κB binding sites, but interact with AP-1 (only K1514), AP-4, and the AML/PEBP2/CBF family of transcription factors. Nothing is known about the changes that occur in maturing macrophages to allow viral expression although replication is known to be dependent on activation of the extracellular signal-related kinase/p38 mitogen-activated protein (ERK/MAP) kinase pathways.

Transmission

There are two important routes of transmission for VMV. The first is respiratory by aerosolized lung exudates between animals that are closely housed and/or in contact for long periods of time. The second is oral by colostrum/milk from infected dams to offspring.

As VMV is usually cell associated *in vivo* (there are few reports of cell-free virus), it has commonly been thought that the infective moiety in lung exudates and colostrum/milk was virus-infected macrophages or epithelial cells. However, recent data suggest that cell-free virus may be important in respiratory transmission. The presence of cell-free virus in the lining fluid of lungs with severe lesions has been shown and the lower lung is a more efficient point of infection than the trachea. Aerosolized particles small enough to reach the lower lung could contain free virus but infected cells would be too large. Once in the lower lung, a variety of possible target cells are present: macrophages (both alveolar and interstitial), dendritic cells, and lung epithelial cells, all of which may allow virus replication.

It is less clear in studies looking at oral transmission of VMV to lambs using colostrum/milk whether cell-free virus or virus-infected cells are important. Induction of lactation corresponds to virus expression in mammary tissue and colostrum contains cell-free virus as well as infected macrophages and epithelial cells. In a transmission study in lambs infected naturally by colostrum, ileal epithelial cells at the tips of the villi were important in early viral replication with virus antigen expression also seen in mononuclear cells in the lamina propria (macrophages), Peyer's patches, and mesenteric lymph nodes (macrophages and dendritic cells). Cell-free virus in colostrum may infect epithelial cells, but these cells could also transcytose viral particles. Similarly infected cells, especially macrophages in colostrum/milk, could transcytose into the lamina propria or beyond to infect the lamb. The appearance of infected mononuclear cells in the lamina propria within 10 h suggests that this route of infection also occurs. Therefore both cell-free and cell-associated virus could infect lambs via colostrum.

Immunity

Acute Infection Cannulation Model

Immune responses to VMV are slow to be detected in blood after natural infection. Seroconversion may take 6 months to 2 years to occur and sporadic T-cell reactivities in peripheral blood lymphocytes are often reported. However, when infection is studied in an acute infection cannulation model (**Figure 2**), immune responses are detected much earlier. The induction of antibody specific for Gag p25 can be shown within 4 days by enzyme-linked immunosorbent assay (ELISA) and neutralizing antibody (presumably specific for Env) within 10 days in efferent lymph. T-cell reactivity (by proliferation to Gag antigen and VMV-specific cytotoxic T-lymphocyte precursors (pCTLs)) is detected within 7–15 days. A low percentage of sheep also show directly active cytotoxic T lymphocytes (CTLs) in efferent lymphocytes. Therefore the kinetics of the immune response to VMV are within normal ranges seen to other viruses. However, it takes

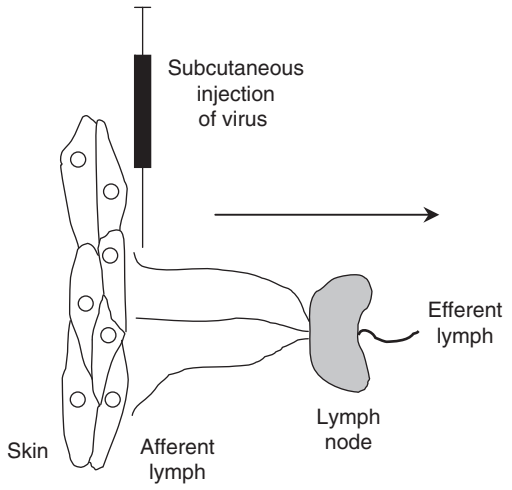

Figure 2 Lymphatic drainage diagram. The acute infection cannulation model for VMV infection of sheep uses subcutaneous injection of virus. The cellular drainage from the site of infection may be collected by cannulation of the lymphatic vessels draining the area. The lymph node directly draining the site of infection may also be biopsied. Lymphatic drainage flows from the tissue through the afferent lymph to the lymph node and then to the efferent lymph (indicated by an arrow). Virus in lymph cells (detectable by 1–4 days) or plasma (none detected) may be quantified, cells carrying virus identified (macrophages and dendritic cells), and immune reactivity monitored (see text). Even using this model, infected cells are at very low frequency, for example, 1 in 10^5–10^6 cells, although increased levels of infected cells rise to a peak by approximately 10–14 days and then decrease to low persistent levels.

much more time for this immune reactivity to be detected systemically. The slow replication rate of VMV and low frequencies of virus-infected cells may be responsible for this weak systemic immune response.

Antibody Responses

In blood, the antibody response is first seen to Gag antigens, in particular capsid antigen p25 (usually 1 month after experimental infection). The anti-Env response develops slowly, but as disease develops it eventually predominates. Other viral proteins also induce antibody responses. Neutralizing antibody responses are targeted to Env and develop very slowly (usually 2–3 months after experimental infection). Virus neutralization causes inhibition of viral binding to the cell (using fibroblasts as target cells) or inhibition of viral reverse transcription and/or integration (using macrophages as target cells). At least five epitopes have been defined in Env by monoclonal antibody reactivity and one immunodominant region is found in transmembrane (TM) Env. There are regions of hypervariability in Env sequences linked to antibody reactivity and escape (see below). VMV-specific antibodies are also detectable in colostrum and milk, cerebrospinal fluid (CSF), and synovial fluid.

Good IgM and IgG1 responses to VMV are induced but in natural infection, sheep do not make an IgG2-isotype response to viral proteins. Persistently infected sheep are able to make an IgG2 response to viral proteins immunized in adjuvant, and it is therefore thought that there may be abnormalities in the antigen-presenting function or T-cell help to B cells during natural infection. This isotype restriction is not seen in goats infected with CAEV; indeed, the predominant isotype induced is an indicator of whether pathology may develop, with strong IgG1 responses to Env SU associated with development of arthritis. The antiviral antibodies induced precipitate viral antigen in agar gel immunodiffusion tests and activate complement but the lack of an IgG2 response is associated with the lack of measurable antiviral antibody-dependent cellular cytotoxicity (ADCC) reactivity in antibody from infected sheep.

T-Lymphocyte Responses

Peripheral blood T-lymphocyte (PBL) proliferative responses to virus antigens are often intermittent with reactivity induced by 1–6 weeks post infection or later, depending on route and amount of virus challenge. Proliferating cells respond to Gag and Env although other viral antigens have not been tested. The response to Gag is mediated by CD4+ T cells. Proliferative T-cell responses to VMV have been detected in CSF by 3 weeks post infection and this reactivity coincides with the initiation of lesion development. Directly active CD8+ CTLs are seen in a low proportion of infected sheep (<20%) but all sheep develop pCTLs (CD8+ T lymphocytes) in their PBL by 3 months after experimental infection. These are induced by day 12 in lymph nodes draining the site of infection and are detectable in lymph nodes and efferent lymph of persistently infected sheep. Infected macrophages can present antigen via MHC class II to stimulate CD4+ T lymphocytes and MHC class I to act as targets for CD8+ CTL as well as to stimulate effector CTL function. Infected macrophages in lesions may therefore present antigen to lymphocytes.

Protective Immune Responses

Protective immune mechanisms have not been defined against VMV. After experimental infection, viral-infected cell frequencies peak, usually 1–2 weeks post infection, and then drop to levels maintained during persistent infection, suggesting that immune mechanisms are induced which control the level of infection. However, experiments to define protective T-lymphocyte subset(s) by *in vivo* antibody depletion of lymphocytes have not been successful at defining protective cell types. Indeed the experiments showed that CD4+ T lymphocytes are required for efficient infection of sheep by

VMV although this lymphocyte subset is not infected. In contrast to the immunodeficiency viruses, no role was detected for CD8+ T cells in control of virus replication. However, the low levels of VMV replication and the return of CD8+ T lymphocytes to the peripheral circulation within 14 days of the start of depletion may mean that sufficient CTL function remained to control the infection. Further work therefore needs to be carried out to investigate protective immune mechanisms against VMV.

Immune Abnormalities

There is no gross immunodeficiency after infection by SRLV; however, there are conflicting reports of immune abnormalities in SRLV-infected animals including changes in total immunoglobulin levels, CD4/CD8 T-cell ratios, decreased suppressor cell activity, and reduced delayed-type hypersensitivity (DTH) responses in skin and increased responses to certain bacterial infections which may be traced to macrophage dysfunction. The specific clinical state of animals is hard to normalize between studies and this may lead to the differing results.

Pathogenesis

Viral Entry

Cell-free virus or virus-infected cells enter the body where they may infect dendritic cells or macrophages in the primary infection site. These cells carry virus to the lymph node where infection is established and then macrophages leaving the lymph node disseminate virus throughout the body leading to a persistent infection. An important tissue for persistent infection of the animal is the bone marrow. Small foci of cells showing restricted replication of VMV have been identified which also express macrophage markers. These are probably myeloid stem cells although no study has defined these well. Infected stem cells may act as a continual source of infected monocyte/macrophages and/or dendritic cells which constantly seed the periphery and tissues. Where the cells mature and express viral antigen, the immune response to the infected cells then causes pathology. Recent molecular data question this theory as very few bone marrow samples from CAEV-infected goats assayed by polymerase chain reaction (PCR) for both proviral DNA and RNA were positive for virus. However, the levels of infection in bone marrow have not been defined well and may be below the detection limit of the assays used. Further work must be done to clarify this point. If bone marrow is not a constant source of infected cells, the virus must be maintained in infected tissues, perhaps lymph nodes and spleen. *In viv*o VMV may be isolated from many tissues including lung, mammary gland, joints, CNS, lymph nodes, spleen, and bone marrow. However, Kupffer cells of the liver are not permissive for virus infection and liver is not involved in pathology of the infection.

Clinical Signs

Infection by VMV does not cause obvious clinical signs for many months and sometimes years (2–5 years). Once clinical signs occur there is a progressive increase in the severity of the clinical signs with time. The diseases caused by SRLV are all typified by chronic active inflammatory processes. Within tissues, there is lymphocyte infiltration and proliferation, and the formation of organized lymphoid follicles and germinal centers. Lesions consist mostly of lymphocytes, macrophages, and plasma cells, often with CD8+ T lymphocytes predominating. This is overlaid with tissue-specific pathology (see **Table 2** for affected organs). Rarely, more acute disease may be seen in younger animals, usually leukoencephalitis, arthritis, or pneumonitis with high mortality.

Viral Cytopathic Effect or Immunopathology?

What causes the gradual buildup of pathology is not clear but it has two contributing factors: the effect of virus infection on infected cell and tissue function and the immune response to the virus. Little is known about the direct effect of virus on tissues although peptide analogs of the *tat/vpr* gene product are neurotoxic in rats and mice transgenic for the *tat/vpr* gene show lymphoproliferative disorders. Indeed, the number of virus-infected cells in lesions is low, so direct viral damage may be minimal.

There is a major immunopathological component to lesion formation. Early studies using immunosuppression reduced the number of CNS lesions seen in sheep infected intracerebrally, although the extent of infection within the CNS was the same, suggesting that direct viral toxicity was not a mediator of pathology. Similarly immunization with viral antigen before or after infection or superinfection with virus often increases the level of pathology seen. There is a positive correlation between virus load and pathology, and it is thought the immune response to viral antigen drives lesion formation. This is difficult to comprehend in early lesions where little virus antigen is detectable but once started, a positive-feedback loop of inflammation and increased virus expression drives progressive damage.

Both lymphocytes and macrophages taken from tissues with pathology show an activated phenotype: for example, they upregulate MHC class I and II, and adhesion molecule expression. However, there is variability in findings with functional assays and cytokine expression as to whether cells are activated or inhibited. Alveolar macrophages from lungs with pneumonitis show increased production of granulocyte monocyte colony stimulating

Table 2 Diseases caused by SRLV

Clinical sign (name)	*Age of animal infected*	*Pathology*	*Infected cells*
Dyspnea/ pneumonia (maedi)	Adult sheep, 2–5 years old Goats, 1–6 months old	Interstitial pneumonitis with perivascular infiltrates; lymphofollicular hyperplasia (some with germinal centers) around vessels, bronchi, and bronchioles; smooth muscle hyperplasia near terminal bronchioles and alveolar ducts	Type I and II pneumocytes, interstitial and alveolar macrophages, endothelial cells and fibroblast-like cells Cell-free virus in lung lining fluid
Wasting and ascending paralysis (visna)	Adult sheep, 2–5 years old Goats 1–6 months old	Periventricular encephalitis (white matter) with perivascular cuffing and infiltration of the parenchyma by mononuclear cells; focal demyelination in brain and spinal cord; meningitis; areas of necrosis; raised cell numbers in CSF; intrathecal antibody production	Interstitial macrophages, microglial cells, rare endothelial, choroidal epithelial cells and fibroblasts of choroid plexus, astrocytes Cell-free virus in CSF rare
Enlarged, hardened udder ('hard bag')	Adult ewes and does	Indurative mastitis with lymphoid hyperplasia, and plasma cells in glandular interstitium, occasional infiltrates into ductal walls and lumens; periductal proliferation and follicle formation; gradual loss of epithelium; diffuse fibrosis; increased numbers of cells and cellular debris in lumen causing increased somatic cell count in milk	Epithelial cells, macrophages, endothelial cells and fibroblast-like cells infected Cell-free virus in colostrum/milk
Swollen joints, lameness ('big knee')	Goats, 1–2 years old Rare in sheep	Chronic arthritis with hyperplastic synovial membrane; subsynovial mononuclear cell infiltrates (follicle formation with germinal centers); increased synovial fluid with raised numbers of lymphocytes (some macrophages and synovial cells) and IgG1 levels (produced *in situ*); angiogenesis in villi and subintima; areas of cellular necrosis; frequent mineralization; increase in fibrous connective tissue around synovial membranes	Synovial membrane cells, macrophages, fibroblasts, endothelial cells. Cell-free virus in synovial fluid
Other affected organs			
Lymphadenopathy		Cortical hyperplasia (increased T cells); germinal center expansions and increased B-lymphocyte areas	Macrophages (and dendritic cells)
Kidney		Glomerulonephritis and interstitial nephritis; medulla and corticomedullary junction lesions; proliferation of mesangial and kidney endothelial cells; lymphatic clusters and follicles	Tubular epithelial cells, macrophages
Third eyelid		Lymphoproliferative inflammation	Macrophages, and glandular, ductal and surface epithelia
Skin		Decreased DTH responses	

factor (GM-CSF), interleukin (IL)-8, and fibronectin but not IL-6, IL-10, or transforming growth factor (TGF) β. Phenotypic changes seen *in vivo* may be caused by immune activation during the inflammatory reaction; however, some studies on infected macrophages *in vitro* suggest direct viral effects on cytokine expression and function. VMV infection of macrophages causes increased expression of IL-8 mRNA but decreased phagocytic and chemotactic activity. MHC class I and II, and LFA-1 and -3 expression are unaffected by infection. CAEV-infected macrophages show a decreased response to bacterial products: inducible nitric oxide synthase (iNOS), tumor necrosis factor (TNF)-α, IL-1β, IL-6, and IL-12p40 induction are all affected. Infection of cells has also been shown to lead to cell death via apoptosis. Infection of macrophages has a complex effect on function which is also altered by the presence of other cells. Co-culture of VMV-infected macrophages with autologous lymphocytes induces the secretion of lentivirus-induced interferon (lentiferon). This is probably a mixture of interferon (IFN)-α and IFN-γ. Effects of lentiferon include inhibition of proliferation and maturation of monocytes and

of virus assembly in infected cells, thus decreasing virus replication, but it also increases MHC class II expression on macrophages which may contribute to lymphoproliferative responses.

The cytokines important in upregulating versus inhibiting VMV expression are poorly understood, partly due to the lack of purified ovine cytokines. Only GM-CSF has been shown to increase VMV transcription and antigen production in macrophages. GM-CSF and TNF-α treatment of cells increases CAEV LTR promoter activity and so may cause increased virus replication. However, there is mixed evidence as to the role that type I IFN plays against VMV infection: pretreatment of choroid plexus cells with a source of ovine type I IFN does not inhibit VMV replication, while pretreatment of cells with human IFN-α does block replication. *In vivo* treatment of lambs early in infection with IFN-τ reduces virus replication and disease development. Although not a cytokine, NO is also known to inhibit virus replication in macrophages.

Autoimmunity

The lesions caused by SRLV in the CNS and joints are very similar to those seen in multiple sclerosis and rheumatoid arthritis of humans. These have links to autoimmunity, and indeed autoimmunity would explain the chronic development of pathology seen in these infections. However, there is very little evidence for this as a mechanism of lesion formation with VMV. There is no response to myelin basic protein (lymphocytes or antibody) or lipid antigen (antibody) in sheep with visna although elevated levels of autoimmune antibody (specific for rheumatoid factor, single-stranded DNA (ssDNA), and cardiolipin) in serum have been detected in infected sheep.

Role of Lymphocytes

CD4+ T lymphocytes are important in promoting infection and lesion formation. At the time of acute infection, CD4+ T lymphocytes are necessary for efficient establishment of infection and later lymphocytes are necessary for lesion development. Therefore, immune responses to unrelated antigens, whether secondary infections or experimental immunizations or vaccinations, may cause increased inflammatory reactions that accelerate lesion development.

Role of the Host and Virus Genetics

Breed resistance to infection and disease development has been documented in sheep and goats. In sheep, the Icelandic breed was particularly susceptible to VMV infection and development of visna, while the Karakul flock, from which infected animals introduced the disease to Iceland, never showed signs of disease. Border Leicester rams are resistant to visna but develop arthritis. This and agricultural practice (e.g., are animals milked?) may explain, in part, the geographical distribution of clinical signs of VMV infection; for example, Iceland commonly saw pneumonitis and encephalomyelitis, UK usually notes pneumonitis, and Spain has documented pneumonitis and mastitis. With interspecies transmission of SRLV, it is not clear whether strains more closely resembling VMV in goats will cause increased incidences of pneumonic disease or whether it is goat genetics which determines joints as a major site of lesion development. In USA, the VMV strains isolated are more closely related to CAEV than European VMV strains and yet pneumonia is still commonly seen in sheep. In goats with CAEV, where only $\sim$30% of animals develop arthritis, linkages to certain MHC class I alleles have been associated with development of disease.

Strains of virus that can be differentiated phenotypically *in vitro* can cause different patterns of lesion development. Usually strains growing to high titer and causing cytopathic effects in macrophages are the most virulent *in vivo*. Strains selected for increased neurovirulence grow better in sheep choroid plexus cells than those that cause pneumonia. This is linked to LTR sequence variation. Therefore, both host and viral genetics are important elements in disease progression.

Immune Evasion

SRLVs persist in the host despite an immune response that includes antibody, CD4+, and CD8+ T lymphocytes. Several mechanisms of viral immune evasion have been noted that may allow this to occur. First, integration into the host genome allows latent infection and persistence in cells without expression of antigen. Similarly, gene expression is tightly regulated with no expression of antigen in immature macrophages. Thus these cells are invisible to the immune system. Second, low-titer neutralizing antibody responses producing low-affinity antibody mean that virus may be able to dissociate from antibody and infect cells. Third, neutralization escape mutants have been shown to emerge during infection. Mutants arise by point mutation in Env, one of the first documented incidences of antigenic drift in viruses. Later, the neutralizing antibody response may broaden to include these mutants. It is thought these mutants have a selective advantage and help the virus to persist in the host. Whether escape mutants are important in VMV pathogenesis is debatable as the original parental virus may be isolated late after infection, showing it has not been cleared from animals and replaced by the mutants. Similarly, neutralization mutants arise when antibody is not present, and their presence is unrelated to severity of pathology. Fourth, the ability of VMV to cause cell fusion means that

cell-free virus is not required (and very rarely seen *in vivo*) as virus may pass from cell to cell directly and so is not exposed to antibody. Fifth, antibody-mediated enhancement of infection of macrophages has been shown in which antibody-coated virus is taken up into macrophages via Fc receptors, thus increasing the effective viral dose. Sixth, there is no ADCC response to the virus. Seventh, although technically not immune evasion, the virus uses the CD4+ T-cell response to help replication, either by activation of macrophages or attraction of macrophages to the relevant tissue.

Control

Because of its insidious nature, control of VMV infection is difficult. Due to the economic losses and animal welfare problems that the disease causes, control programs are in place in many countries. These are based on serological tests, usually ELISAs (often to capsid p25 and TM Env) or agar gel immunodiffusion tests. However, because of the length of time taken for induction of a detectable antibody response in blood, and the possibility of fluctuations in the response, testing regimes involve repeated tests to maintain accreditation of SRLV-free status. PCR has not been used routinely for VMV diagnosis due to the strain variation that is present within SRLV and the low provirus load in blood of persistently infected animals.

Several options are open to try to derive SRLV-free flocks. Iceland eradicated the disease in the 1940s and the 1950s by culling all infected flocks and restocking from SRLV-clean animals. Others have used removal of serologically positive animals (and their progeny) from the flock after each test round until serologically free status is achieved. In the Netherlands, there was a successful policy of re-deriving flocks from 'snatched' lambs. These are lambs taken at birth from their mothers before they suckle infected colostrum. The lambs are then hand-reared on either heat-inactivated or bovine colostrum. Once VMV-free flocks are achieved, careful control of importation of animals into flocks/countries is necessary to maintain this status, as it is importation of infected asymptomatic animals that then live in close contact with the host flock that often leads to spread of infection into previously free areas, for example, Iceland (1933) and Finland (1981). With proof now of interspecies transmission, SRLV-free status will only be maintained if both sheep and goats are kept separate or both species kept SRLV free.

Treatment and Vaccination

At present, there is no treatment against infection although certain anti-retroviral drugs do have activity against VMV. There have now been several vaccination studies using inactivated virus preparations, live-attenuated viruses, and subunit vaccines administered by a variety of vectors, for example, protein, plasmid, and vaccinia virus, using a variety of routes and different adjuvants or cytokine immunomodulators. None has produced sterilizing immunity and some have increased the levels of pathology seen. Induction of neutralizing antibody by immunization with recombinant Env has proven problematic using baculo- and vaccinia virus-expressed antigen in sheep. The best result has been with bacterial-expressed Env gp70 but only low titers of antibody were seen using this immunogen. Some vaccines have reduced virus load early in infection but pathology has still developed, although in some cases this is less severe than control animals. The most promising result has come from CAEV in goats using DNA prime and then protein boost with Env in Freund's incomplete adjuvant. There was decreased viral replication in lymph node and synovium, and reduced development of severe arthritis for more than 18 months using this vaccine.

The possibility of inducing antibody that enhances the ability of virus to infect macrophages, the induction of CD4+ T lymphocytes responses that may increase the efficiency of the primary infection, as well as increasing the pathological response are all aspects of the immune response to VMV that needs much further study before a successful vaccine will be released to the field.

Conclusions

VMV has many features in common with the other lentiviruses including infection of macrophages and dendritic cells. There is now an understanding of the type of lesion VMV induces in many tissues. However, there is still much work to be done with VMV to answer questions on sites of persistence of the virus, triggers of lesion development, protective immune responses, and vaccine control of the infection.

Glossary

Mild-strain cross-protection A plant systemically infected by a mild virus strain will not develop additional symptoms when inoculated by a severe strain of the same virus. Most often, the severe strain does not multiply in the cross-protected plant.
Filiformy A leaf deformation symptom in which the leaf blade is drastically reduced but not the veins, giving a shoestrings aspect to the leaf.
Transmission propensity A measure of vector importance quantifying the natural ability of a species to inoculate a plant with a virus under conditions that allow vectors to move and feed freely.

History and Taxonomy

Watermelon Mosaic Virus

Mosaic diseases of cucurbit crops were first reported in the 1920s and the early literature contains a diversity of names for viruses or virus diseases that were only partially characterized. In 1940, Milbrath reported a severe watermelon (*Citrullus lanatus*) mosaic disease in California, but the nomenclature of the causal agent remained controversial until 1979. In 1965, Webb and Scott compared ten isolates from southern USA of what was then called the watermelon mosaic virus (WMV) complex. Based on cross-protection experiments, serological relationships and host range reactions they divided them into two groups: WMV1 and WMV2. WMV1 and WMV2 were considered as different viruses, also different from a watermelon mosaic isolate reported from South Africa in 1960 by van Regenmortel. Further work by Milne and Grogan in 1969 increased the confusion by concluding that WMV1 and WMV2 were strains of the same virus. In 1979, Purcifull and Hiebert definitively clarified the situation by demonstrating that WMV1 and WMV2 were indeed serologically distinct entities, and that WMV1 was closely related to papaya ringspot virus (PRSV). Today, WMV1 is considered as the W strain of PRSV, while WMV2 is referred to as watermelon mosaic virus (WMV). In addition, the same authors showed that a watermelon mosaic virus isolate from Morocco was a third serological entity. This isolate is considered as a distinct virus, Moroccan watermelon mosaic virus (MWMV), to which probably also belongs the South African isolate.

So, from the initial watermelon mosaic virus complex emerged three different virus species: *Watermelon mosaic virus*, *Papaya ringspot virus*, and *Moroccan watermelon mosaic virus*.

Zucchini Yellow Mosaic Virus

An apparently new cucurbit virus was isolated in 1973 from a zucchini squash (*Cucurbita pepo*) plant in Northern Italy, and Lisa *et al.* described this virus as belonging to a new potyvirus species, *Zucchini yellow mosaic virus*, in 1981. In 1979, many melon (*Cucumis melo*) crops were devastated in southwestern France by an apparently new virus disease, whose causal agent was tentatively named muskmelon yellow stunt virus; very rapidly, it appeared that it was a strain of zucchini yellow mosaic virus (ZYMV). Within a few years, ZYMV was reported in many countries on the five continents, and in this regard, ZYMV appears as a typical example of an emerging plant virus.

Classification

Based on particle morphology, aphid transmissibility, serological relationships, ability to induce pinwheel cytoplasmic inclusions in host cells, genome organization, and nucleotide sequences, WMV and ZYMV were identified as members of the genus *Potyvirus*, family *Potyviridae*. Several other potyviruses have been shown to infect

cucurbit crops including PRSV-W, MWMV, zucchini yellow fleck virus (ZYFV), melon vein banding mosaic virus (MVBMV), telfairia mosaic virus (TeMV), turnip mosaic virus (TuMV), clover yellow vein virus (ClYVV), and bean yellow mosaic virus (BYMV). However, these viruses have either only limited geographic distribution or minor economical incidence.

Molecular analyses based on the coat protein (CP) coding sequence revealed that cucurbit-infecting potyviruses belong to several 'clusters' of closely related species: ZYMV and WMV belong to a cluster that also contains mostly legume-infecting potyviruses, whereas PRSV, MWMV, and ZYFV are grouped in a 'PRSV-like' cluster containing mostly cucurbit-restricted viruses (**Figure 1**).

Symptoms

Watermelon Mosaic Virus

WMV induces a diversity of symptoms according to the isolate and the host cultivar. On leaves, symptoms are mosaics, vein banding, more or less severe leaf deformations, and filiformy. Some isolates induce discoloration and deformation on fruits of zucchini squash susceptible cultivars while other isolates do not affect fruit and yield quality. Mosaic and discoloration are also observed on leaves and fruits of some melon cultivars (**Figure 2**).

Zucchini Yellow Mosaic Virus

Since its first detection, ZYMV was recognized as a virus causing extremely severe symptoms leading to complete yield losses in the case of early contamination. This severity of symptoms was probably an important factor for the rapid identification of ZYMV soon after its first outbreaks, in many countries. In melon, leaf symptoms include vein clearing, yellow mosaic, leaf deformation, occasionally with blisters and enations. There is often a severe plant stunting. Some ZYMV isolates can induce a rapid and complete wilt in cultivars possessing the *Fn* gene. On fruits, a diversity of symptoms are observed: external mosaic or necrotic cracks, internal marbling, and hardening of the

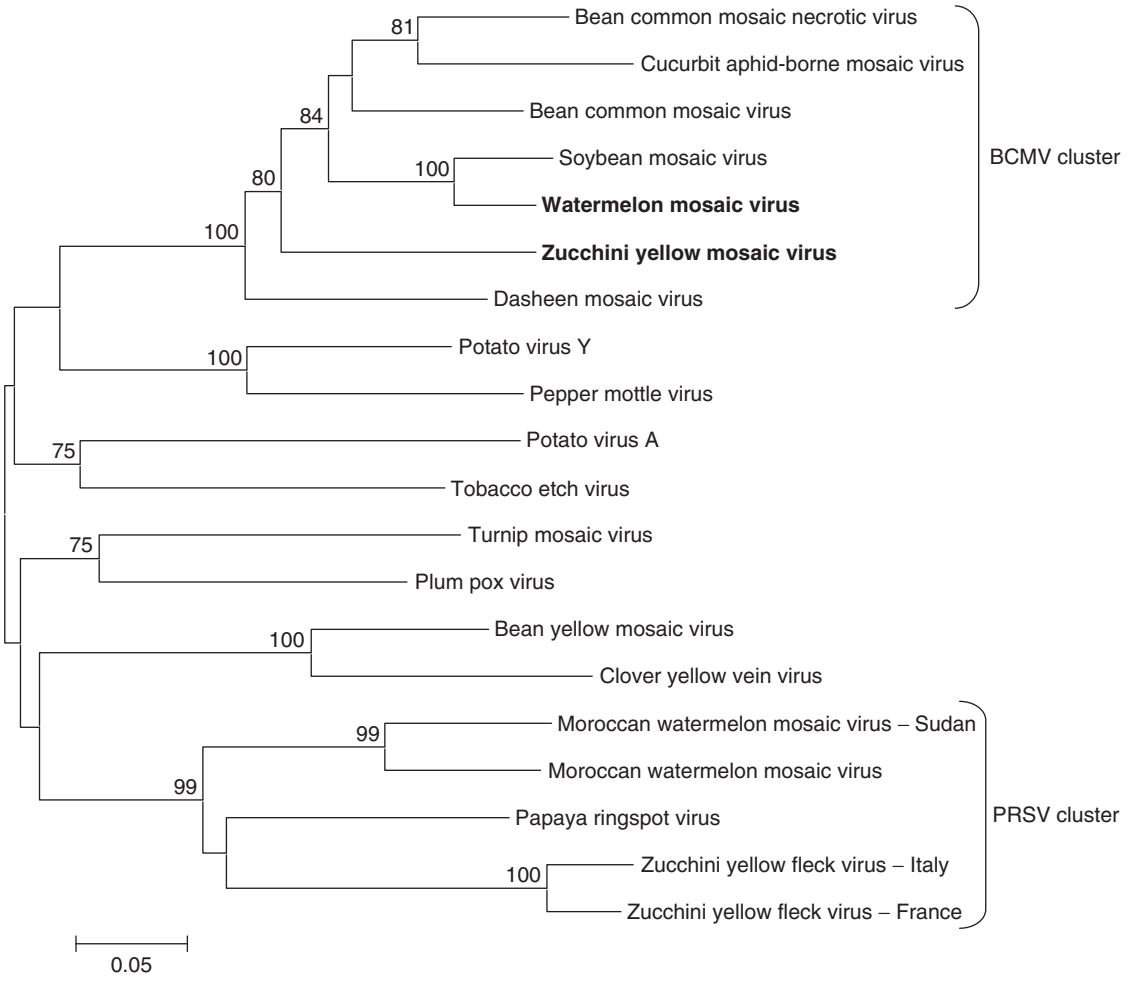

Figure 1 Relationships based on CP amino acid sequences, of cucurbit-infecting potyviruses. Branch lengths indicate the molecular divergence of viruses (the scale bar represents 0.05 mutations per residue). Figures at some nodes represent bootstrap values (in %), indicating the robustness of each node. Only values above 75% are indicated.

Figure 2 Mosaic symptoms on a leaf and fruit of a melon plant infected by a moderately severe WMV isolate.

Figure 3 Severe mosaic and deformations on leaves and fruits of a zucchini squash plant infected by ZYMV. Reproduced from Astier S, Albouy J, Maury Y, and Lecoq H (2001) *Principes de virologie végétale: Génome, pouvoir pathogène, écologie*. Paris: INRA Editions, with permission from QUAE.

flesh. Seeds are occasionally severely deformed and have poor germination rates. In zucchini squash, symptoms are very severe on leaves with mosaic, yellowing, leaf distortion and sometimes very severe filiformy. Fruits are generally severely misshaped with prominent knobs and are of course unmarketable (**Figure 3**). In cucumber (*Cucumis sativus*) and watermelon, mosaic and deformations are generally observed on leaves and fruits.

Synergism

Synergism has been observed between WMV or ZYMV and other viruses infecting cucurbits which can be expressed either by increase in virus multiplication rates or by more severe symptoms. Significant increase in cucumber mosaic virus (CMV) multiplication rate was observed in cucumber plants co-infected by ZYMV. CMV could also partially overcome a resistance in cucumber when in mixed infection with ZYMV. In grafted cucumbers, double infection by CMV and ZYMV induces a severe and rapid wilting reaction which is not observed with infections by CMV or ZYMV alone. When WMV or ZYMV are in mixed infection with the polerovirus, cucurbit aphid-borne yellows virus (CABYV), CABYV multiplication rate and symptom intensity are increased. As for other potyviruses, these synergetic effects could be related to the strong potyvirus gene silencing suppressor.

Geographic Distribution

Both WMV and ZYMV are now widely distributed in the major cucurbit production areas worldwide. Their geographic distributions are broadly overlapping and frequent mixed infections are observed in the fields.

For unknown reasons, WMV appears to be rare or absent in cucurbits in subtropical or tropical areas. For instance, in exhaustive surveys conducted in Nepal, Sudan, and French West Indies, no WMV was detected, although ZYMV was relatively abundant. In Florida, WMV is frequent in northern and central counties but is not detected in southern counties, whereas ZYMV can be found throughout the state. This cannot be related to a lack of potential WMV vectors or reservoirs because both are abundant in tropical or subtropical areas.

ZYMV is present worldwide in almost all countries where cucurbits are grown, under temperate, Mediterranean, subtropical, and tropical climatic conditions. It affects highly mechanized cropping systems (such a glasshouse crop production in Northern Europe) as well as more traditional agroecosystems (such as flood-irrigated crops on the Nile banks). ZYMV has been reported in very remote areas including semi-desertic regions or islands.

Host Range

WMV has a relatively wide experimental host range for a potyvirus. It infects over 170 species in 26 mono- or dicotyledonous families. Besides cucurbits, WMV causes mosaic diseases in legumes (pea, broad bean) and orchids (vanilla, *Habenaria radiata*) and infects many weeds that can serve as alternative hosts. Generally, naturally infected weeds do not present evident symptoms of viral infection.

ZYMV has a relatively narrow host range. In natural conditions, it infects mostly cultivated or wild cucurbits but also a few flower species (*Delphinium*, *Althea*) or weeds.

Diagnostic Method

The confusion that was prevalent in the early descriptions of watermelon mosaic diseases was mainly due to

the convergence of symptoms caused by WMV, PRSV, and MWMV in cucurbits and to the lack of proper diagnostic tools. Symptoms and virus particle morphology were clearly insufficient to differentiate these viruses. The production of specific polyclonal antisera, and the development of simple serological tests, such as the gel double-diffusion test in agar containing sodium dodecyl sulfate and sodium azide (SDS-ID), brought a major contribution to the proper diagnosis of cucurbit potyviruses. In particular, this method contributed to the rapid and unequivocal identification of ZYMV in several countries soon after its first observation. Now, double antibody sandwich enzyme-linked immunosorbent assay (DAS-ELISA) is generalized and commercial kits are available for WMV and ZYMV. Recently, dipstick serological tests based on the lateral flow technique have been developed that allow an easy and rapid diagnosis of ZYMV in the fields.

Monoclonal antibodies (MAbs) have been produced for ZYMV and WMV. They proved to be very useful to study the serological variability and to differentiate ZYMV and WMV subgroups. They have also been used successfully to analyze virus interactions, and in particular cross-protection efficiency and specificity.

Many partial nucleotide sequences are now available for ZYMV and WMV, particularly in the CP coding region, which allowed the development of specific primers for each virus. However, in routine testing, DAS-ELISA seems to be more reliable than RT-PCR.

Vector Relationships

WMV is transmitted by at least 35 aphid species in 19 genera. Fewer aphid species were tested for their ability to transmit ZYMV, and 11 were identified as ZYMV vectors. *Aphis craccivora*, *Aphis gossypii*, *Macrosiphum euphorbiae*, and *Myzus persicae* are efficient WMV and ZYMV vectors. Some aphid species were shown to be poor or nonvectors of WMV and ZYMV, which suggests some level of specificity in the virus–vector interaction.

WMV and ZYMV are transmitted on the nonpersistent mode: they are acquired and transmitted during very short probes (a few seconds to minutes), and their retention period in the vector is relatively short (a few hours).

WMV and ZYMV as typical potyviruses require the presence of a virus-encoded helper component (HC-Pro) protein for transmission. HC-Pro from WMV and ZYMV are interchangeable and both mediate efficiently the transmission of purified virions of both species.

Several ZYMV isolates that have lost aphid transmissibility have been characterized, and a unique feature for this virus is that single amino acid mutants have been identified in the three domains important for transmission. ZYMV-NAT has an A to T substitution in the DAG motif in the CP, ZYMV-PAT a T to A substitution in the PTK motif of HC-Pro, and ZYMV-R1A a K to E substitution in the KLSC motif of HC-Pro. These mutants led to the identification of an interaction between the HC-Pro and CP through their PTK and DAG domains.

The nontransmissible isolate ZYMV-NAT (having the DTG motif in the CP) could be transmitted by aphids from plants infected concomitantly by a transmissible isolate of PRSV. This occurred through heteroencapsidation, a phenomenon by which ZYMV RNA is completely or partially encapsidated by PRSV CP, which is functional in aphid transmission. An aphid nontransmissible isolate deficient for HC-Pro can also be transmitted by aphids when in mixed infection with an isolate that has a functional HC-Pro. The transmissible isolate provides its functional HC-Pro to mediate the transmission of the deficient isolate. These two mechanisms can contribute to the maintenance, in natural conditions, of variants which have lost their vector transmissibility.

An interesting interaction has been observed between ZYMV and *Aphis gossypii*, an aphid vector colonizing cucurbit crops. *Aphis gossypii* lives longer and produces more offspring on ZYMV-infected than on noninfected plants. In addition, more alatae are produced on infected plants, which may stimulate the spread of ZYMV. These phenomena might be related to the observed changes in phloem exudates' composition (free amino acids, sugars) in virus-infected plants.

Epidemiology

Virus Sources

WMV has not been described as seed borne in cucurbits or other crops, but may be transmitted through vegetative propagation in vanilla. ZYMV seed transmission remains controversial. It has been reported in squash but other studies repeatedly failed to observe seed transmission. This is an important issue, since ZYMV seed transmission would be the simplest explanation for the rapid ZYMV dissemination throughout the world in the 1980s. If ZYMV seed transmission does occur, it is at a low rate and may be only for some strains or hosts. Another possible way for long-distance dissemination of ZYMV is through the globalization of vegetable production and trade. It has been shown that ZYMV-infected fruits imported from Central America into Europe could be very efficient virus sources for aphids.

Virus sources from which epidemics will initiate could be overwintering weeds or crops infected during the previous crop season. In tropical and subtropical regions, cucurbit crops or weeds grow all year round, and viruses could easily move from an old infected crop or cucurbit weed to a young planting. In more temperate regions,

non-cucurbit weeds were found to be efficient reservoirs for WMV but not for ZYMV. Winter protected-crops could contribute to ZYMV overwintering in Mediterranean regions and residential gardens were found to be important sources of ZYMV in California.

Efficient Vectors

Many potential aphid vector species have been identified for WMV and ZYMV. A study was conducted to compare the vector capacity of two aphid species, one colonizing cucurbits (*A. gossypii*), the other not (*A. craccivora*). Two parameters were used. Transmission efficiency was measured in the laboratory with single aphids exposed in sequence to an infected plant and then to four healthy plants. Transmission propensity was measured by arena tests (more representative of natural conditions) in which aphids could move between plants and feed without interference. It was shown that *A. craccivora* had both a higher efficiency and propensity to disseminate ZYMV than *A. gossypii*. This highlights the importance of noncolonizing transient vector species in the epidemiology of ZYMV.

Pattern of Spread

The same general pattern is observed for WMV and ZYMV. The first contaminations occur generally shortly after planting, depending upon the availability of virus sources in the environment. The secondary virus spread then occurs when aphid flights, particularly of noncolonizing species, spread the virus from the primary infection foci to the rest of the crop. The diseased plants are often distributed in large patches that rapidly extend and join each other, leading to the complete contamination of the crop within a few weeks. Simultaneously, the infected crop will serve as a source of virus to contaminate weeds or nearby young plantings. Epidemic development curves have an overall S-shape, generally fitting well with the logistic model.

Control Methods

Prophylactic Measures

Prophylactic measures are intended to prevent or limit the contact of viruliferous aphids with cultivated plants. They are not specific for a particular virus and are generally efficient for all aphid-borne viruses. These include careful weeding near plantings and avoiding overlapping crops in the same area to reduce virus and aphid sources near new plantings. Plastic mulches have a repelling action on aphids and significantly delay WMV and ZYMV spread. However, they confer only a temporary protection that is limited to the early stages of the crop, because their efficiency decreases when plant growth covers their surface. Row covers of different types (unwoven, perforated plastics, etc.) can also be used; they physically prevent winged aphids from reaching the plants, but they must be removed to allow insect pollination necessary for cucurbits. Both methods have a major drawback: they require a lot of plastic material that farmers must dispose in an environmentally sound way after the crop cycle. Insecticides applications have generally been found inefficient in limiting WMV and ZYMV spread. This is to relate to the large number of winged aphids that land on the plants and to the rapidity of the transmission process. Oil applications can delay virus spread when inoculum pressure is moderate. When applicable, a 1 month crop-free period has been shown to be efficient in limiting ZYMV virus spread.

Cross-Protection

Although the mechanism of cross-protection has not been fully elucidated (it probably relies on the gene silencing machinery), this method has been developed at a commercial level to protect cucurbit crops against ZYMV. The principle is simple (**Figure 4**): when a mild virus isolate (i.e., that has no significant impact on commercial yield) is inoculated to young seedlings, it protects the plant from subsequent contaminations by severe isolates of the same virus. The mild strain ZYMV-WK is a natural variant of a severe aphid nontransmissible isolate. Although efficient against most ZYMV isolates, ZYMV-WK does not protect against very divergent isolates such as those from Réunion Island, indicating some specificity in the protection. A single amino acid change (R to I) in the FRNK conserved domain of the HC-Pro is responsible for symptom attenuation of ZYMV-WK. A complete technological package (mild strain production, quality control protocols, inoculation machines) has been developed to implement commercially ZYMV cross-protection. Mild WMV isolates have been reported that could also have a potential for cross-protection.

Resistant Cultivars

The use of virus-resistant cultivars is probably the easiest and cheapest way to control plant viral diseases at the farmer's level. Breeding for resistance still relies mainly upon searching for resistance characters in germplasm collections and introgression of the resistance gene(s) into commercially acceptable cultivars. Considerable efforts have been made to look for resistance to WMV and ZYMV in genetic resources, and some WMV- or ZYMV-resistant commercial cultivars are now available. Some resistance genes confer complete and durable resistance (such as the *zym* gene in cucumber), while others confer only partial resistances or may be overcome by virus evolution (such as the *Zym* gene in melon). An

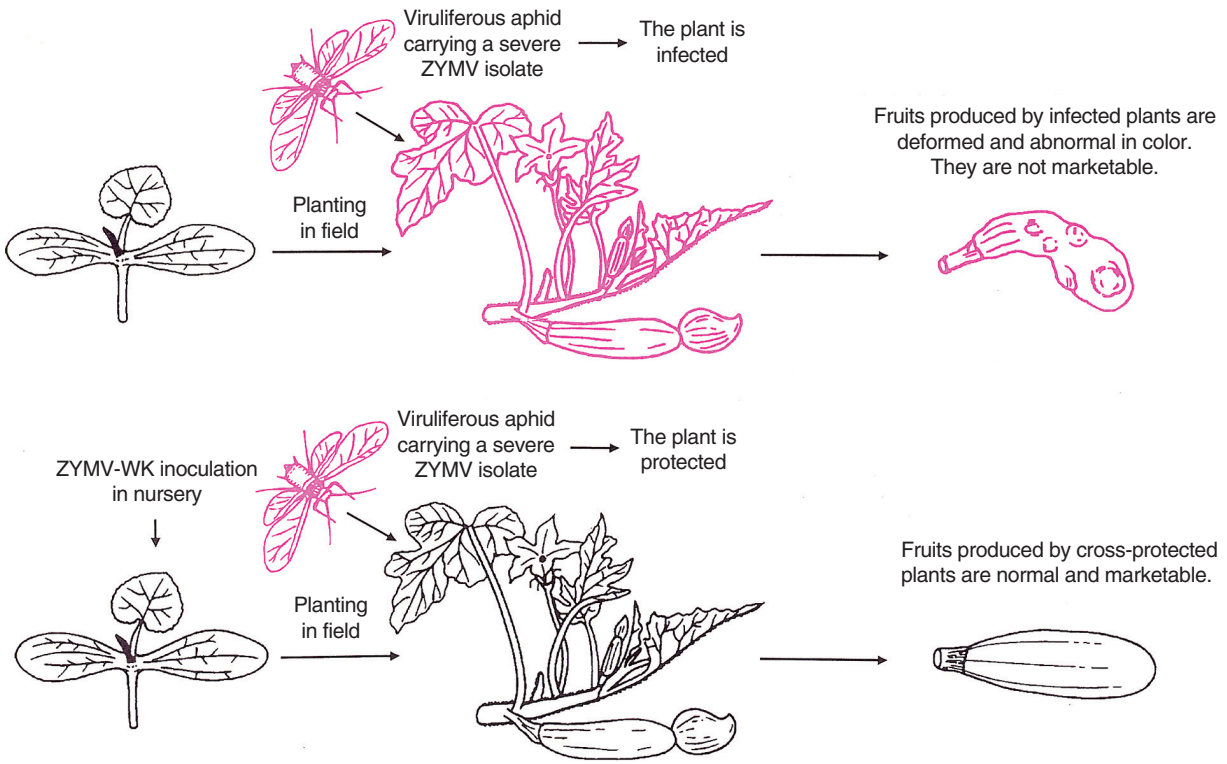

Figure 4 Representation of mild strain cross-protection as applied with ZYMV-WK in zucchini squash. Reproduced from Astier S, Albouy J, Maury Y, and Lecoq H (2001) *Principes de virologie végétale: Génome, pouvoir pathogène, écologie*. Paris: INRA Editions, with permission from QUAE.

interesting situation is observed for ZYMV resistance in squash. Although the resistance level was high in the original accession of *Cucurbita moschata* in which the resistance was identified, when transferred through interspecific crosses to zucchini squash (*C. pepo*), the resistance phenotype was different: ZYMV multiplies but the plants present only very mild symptoms (a phenomenon called tolerance). However, tolerance appears not to be stable since aggressive variants of the virus (i.e., causing severe symptoms in tolerant plants) may emerge in these plants. A single amino acid change in the P3 gene is sufficient to confer this aggressive phenotype. However, the aggressive variants are counter-selected when in competition with common ZYMV isolates in susceptible cucurbits. This genetic load associated with aggressiveness could be a factor that will make the tolerance durable. In melon, a resistance to WMV and ZYMV transmission by *A. gossypii* was found to be governed by the single dominant gene *Vat*. This gene is present in many commercial cultivars, but confers only limited protection in the fields, probably because WMV and ZYMV are also transmitted by many other aphid species in natural conditions.

In the last two decades, attempts were made to obtain WMV and ZYMV transgenic resistant plants using the pathogen-derived resistance approach. Different constructs were tested to obtain resistant WMV or ZYMV plants and the best results were obtained with the full-length CP gene and with ribozymes. Freedom II, a transgenic squash hybrid containing the WMV and ZYMV CP genes, was released in the USA in 1995, as the first virus-resistant transgenic crop to be commercially cultivated in the world. It proved to have a very efficient resistance to WMV and ZYMV in field conditions. Similar biotech crops are presently grown mainly in southeastern USA, particularly during late summer and fall when WMV and ZYMV inoculum pressure is high.

Variability

Only limited biological variability has been reported for WMV. This concerns mainly differences in symptom intensity, host range, or aphid transmissibility. In contrast, from its first description, ZYMV appeared to have a very important biological diversity. When collections of field isolates were compared, an important variability was revealed in host range and symptoms on susceptible hosts, with isolates producing mild or atypical mosaic symptoms, necrosis, or wilting reactions. When these isolates were inoculated to melon or squash varieties possessing resistance genes, different pathotypes could be differentiated. Important variability has also been observed in aphid transmissibility and several aphid nontransmissible or poorly transmissible isolates have been described.

Limited serological variability was observed in WMV and ZYMV when polyclonal antibodies were used. However, the development of monoclonal antibodies against WMV and ZYMV allowed the characterization of serotypes closely correlated to the molecular variability.

The molecular variability of ZYMV and WMV was assessed mostly on the CP region, particularly the N-terminal part of the CP that is known for potyviruses to be highly variable and is frequently used for molecular studies. More than 200 partial CP sequences are now available for ZYMV. Strains from some regions, for example, Réunion Island and Singapore, are highly divergent molecularly, whereas isolates from other regions are more closely related, and fall into three main clusters without geographic structure; more recent sequence data available for Asian strains (China, Korea, Taiwan) indicate that some of those strains tend to locate between previously described groups or clusters. Molecular analyses have allowed, in a few cases, tracking the putative origins of ZYMV strains emerging in a new area.

Genetics and Evolution

WMV and ZYMV genome organization is very similar to that of other potyviruses sequenced so far. The single-stranded, positive-sense RNA genome (9.6 kbp for ZYMV, 10 kbp for WMV excluding the polyadenylated 3′ extremity) is translated as a single polyprotein that is self-cleaved in 10 functional proteins.

The full-length sequence revealed that WMV is related to the legume-infecting soybean mosaic virus (SMV); however, the P1 protein is 135 amino acids longer than that of SMV, and the N-terminal half of P1 shows no relation to SMV but is 85% identical to another legume-infecting potyvirus, bean common mosaic virus (BCMV). This suggests that WMV has emerged through an ancestral recombination event between an SMV-like and a BCMV-like potyvirus. SMV and BCMV have narrow host ranges, mostly restricted to legumes, while WMV is one of the potyviruses with the broadest host range, including monocots and dicots. The impact of its recombinant nature on WMV biological properties remains unknown and speculative.

Partial sequence data also indicate the presence of intraspecific recombinants in WMV: the molecular variability was structured in three groups based on the CP sequence; when other parts of the genome were considered, several isolates switched groups, indicating that recombination may have taken place. By sequencing the full-length genome of putative recombinants, recombination points were characterized in different parts of the genome.

In the case of ZYMV, sequence analysis softwares suggest that recombination might have taken place, but the situation is not as clear-cut as for WMV.

Besides recombination, viral genomes also evolve by mutations that take place during replication. In the case of ZYMV, the biological consequences of several point mutations that emerged in natural conditions were assessed by molecular studies: sequences of closely related strains with different biological properties were compared, and the mutations observed – particularly non-silent mutations located in conserved domains – were introduced by site-directed mutagenesis in an infectious cDNA of ZYMV in order to check if the mutation alone is sufficient to induce the difference in biological properties.

Molecular studies have thus shown that single point mutations in HC-Pro or P3 of ZYMV were important for symptoms. Similarly, single mutations in HC-Pro or CP greatly affect aphid transmissibility. For unknown reasons, some ZYMV isolates such as ZYMV-E15 seem to be particularly prone to mutations and many variants (mild, aphid nontransmissible, aggressive, or virulent) have been derived from this isolate.

Biotechnological Application

The development of infectious cDNA clones of ZYMV brought the possibility of using ZYMV as a biotechnological tool to produce proteins of pharmaceutical or crop protection interest. The gene coding for the protein of interest can be inserted in the ZYMV genome either between the P1 and HC-Pro domains or between the NIb and CP domains. For optimal protein production, there is the possibility to use mild clones that have the mutation in the FRNK motif of HC-Pro so that they produce mild symptoms and do not affect plant growth. The protein may be produced in the edible cucurbit fruits, and therefore used directly for oral administration. Several molecules of pharmaceutical interest have been efficiently produced through this technology: the human interferon-alpha 2, antiviral and antitumor proteins MAP30 and GAP31, and a mite allergen. This technology also provided a way to produce large amounts of nucleocapsid proteins of five tospoviruses that could be used for immunization and production of specific antibodies. Finally, the *bar* gene coding for a phosphinothricin acetyltransferase that confers resistance to herbicides based on glufosinate ammonium has been inserted into the mild ZYMV expression vector. In weed-infested plots, this construct efficiently protected inoculated zucchini squash plants from damage caused by a herbicide treatment that completely destroyed the weeds. In addition, these plants were protected against severe ZYMV isolates. It is interesting to see that ZYMV, which emerged as the most damaging cucurbit virus in the last decades, can be manipulated and used for the benefit of human health and agriculture.

Glossary

Bridge vector Competent mosquito vector that becomes infected following feeding on vertebrate hosts within the enzootic transmission cycle, and subsequently infects humans and other incidental hosts.

Enzootic A pathogen that is constantly present in an animal population, but usually only affects a small proportion of animals at any one time.

Epidemic Severe outbreak within a region or a group of humans.

Epizootic An outbreak of disease affecting many animals of one kind at the same time.

Extrinsic incubation period Period of time required for mosquito to transmit virus after ingesting infectious blood meal.

Neuroinvasive disease Disease caused by pathogen that infects nerve cells.

Nonviremic transmission Viral transmission to uninfected arthropod in the absence of detectable replication of virus in the vertebrate host.

Pathogenesis Origin and development of disease; more specifically the cellular events and reactions and other pathologic mechanisms occurring in the development of disease.

Phylogenetic analysis A method developed by biological systematists to reconstruct evolutionary genealogies of species based on nucleotide sequence relatedness.

Vertical transmission Viral transmission from adult female arthropod to her immediate progeny.

Viremia The presence of virus in the blood.

Zoonosis Also called zoonotic disease; refers to pathogens that can be transmitted from animals, whether wild or domesticated, to humans.

Classification

West Nile virus (WNV) is a member of the family *Flaviviridae*, genus *Flavivirus*, which is composed of approximately 70 members classified into 12 antigenic subgroups. The family *Flaviviridae* includes two additional genera,

Pestivirus (including veterinary pathogens such as bovine viral diarrhea viruses) and *Hepacivirus* (including the human pathogen hepatitis C virus). WNV belongs to the Japanese encephalitis (JE) antigenic complex, which includes the human pathogens St. Louis encephalitis, Rocio, and Ilheus viruses in the Americas, Japanese encephalitis virus in Asia, Murray Valley encephalitis virus in Australia, and other viruses, most of them not associated with encephalitis.

History and Geographic Distribution

WNV was first isolated in 1937 from the blood of a febrile woman in the West Nile district of Uganda. The next evidence of activity occurred when WNV was isolated from mosquitoes and birds and identified as the etiologic agent in sick children in North Africa and the Middle East in the 1950s. West Nile neuroinvasive disease (WNND) was first recognized during an outbreak in elderly patients in Israel in 1957. In the 1960s, WN encephalitis in equines was recognized in Egypt and France. The largest outbreak of WN fever occurred in 1974 in Cape Province, South Africa, leading to approximately 10 000 cases. Increasing frequency of severe outbreaks began occurring in 1996 in humans and horses, largely in the Mediterranean Basin. The range of WNV expanded suddenly in 1999 with the introduction of the virus into the New York City area, although the mode of introduction is unknown. The virus became successfully established as it expanded its range westward to encompass the contiguous United States, northward into Canada in 2001, and southward beginning in 2002 into Mexico, Central America, the Caribbean and parts of South America. From 1999 to 2006, approximately 22 790 cases of WN disease were reported in the US. The largest epidemics of neuroinvasive disease caused by WNV in North America occurred in 2002 and 2003 in the US, when 2946 and 2866 cases, respectively, of WNND were identified. WNV disease also has been noted in Cuba and Argentina in addition to the US and Canada in the Western Hemisphere, but scant evidence of morbidity and mortality has been observed in tropical America. Possible reasons for the lack of overt disease in tropical America are cross-protection from other flaviviruses circulating in tropical regions, less virulent strains of WNV, less-competent arthropod and avian hosts than in temperate regions, and greater diversity of host species in the tropics.

Molecular Epidemiology

WNV is the most widely distributed flavivirus in the world (**Figure 1**). Isolates comprise two main lineages based on nucleotide sequence homology (**Figure 2**). Lineage 1 includes three clades: (1a) isolates from Africa, Asia, Europe, Middle East, North America, and Russia; (1b) isolates from Australia (Kunjin); (1c) most Indian isolates. The strain of WNV introduced into the US in 1999 has 99.7% homology in both nucleic acid and amino acid sequence with a 1998 Israeli goose isolate. Lineage 2 contains strains isolated in sub-Saharan Africa and Madagascar, and includes the prototype 1937 Ugandan isolate. Severe WNND in humans has been associated only with lineage 1 strains. The strain responsible for the South African WN fever outbreak in 1974 is in lineage 2. Comparison of isolates from lineage 1 indicates differences in virulence between North American and Afro-European strains, but the degree of difference varies with the specific avian host. Enhanced virulence of the North American strains appears to be partially correlated with envelope (E) protein glycosylation. Strains within lineage 2, while not associated with overt human outbreaks, also vary phenotypically with respect to virulence in animal models. Two potential new lineages have been identified recently; a lineage 3 virus was isolated from *Culex pipiens* in the Czech Republic (Rabensburg virus) in 1997 and 1999, and a lineage 4 virus isolated from *Dermacentor marginatus* ticks in Russia in 1998 (LEIV-Krnd88–190). Rabensburg virus showed 77–78% identity to lineage 1 and 2 WNV strains, 77% identity to strain LEIV-Krnd88–190, and 71–76% identity to other representatives of the JE antigenic complex.

Phylogenetic analyses of WNV isolates from the US indicate that the virus remains highly conserved genetically. A single conserved amino acid change in the E gene (V159A), first detected in 2001, occurred with increasing frequency from 2002 through 2004 throughout the US (**Figure 3**), and became the dominant genetic variant circulating throughout North America. This genotype, 'North American dominant', probably resulted from a random mutation that became fixed in the viral RNA of the originally introduced genotype, 'Eastern US' strain. The dominant genotype disseminates 2–4 days earlier following feeding, in *Culex* spp. mosquito vectors, effectively reducing the extrinsic incubation period and thereby increasing the reproductive ratio or R_0 of WNV. This reproductive advantage, and a higher viremia observed in some avian species, may have contributed to displacement of the Eastern US genotype. Temporal and spatial clustering of isolates suggest the occurrence in some cases of localized virus spread by mosquitoes or resident birds, and in others long-distance dispersal by migratory birds or possibly by human transport. Nonetheless, it is clear from the phylogenetic evidence based on US isolates that there was a single introduction of WNV into North America from the Old World. This is in contrast to WNV in Israel, where both lineage 1 and 2 strains are frequently introduced, most likely during bird migration.

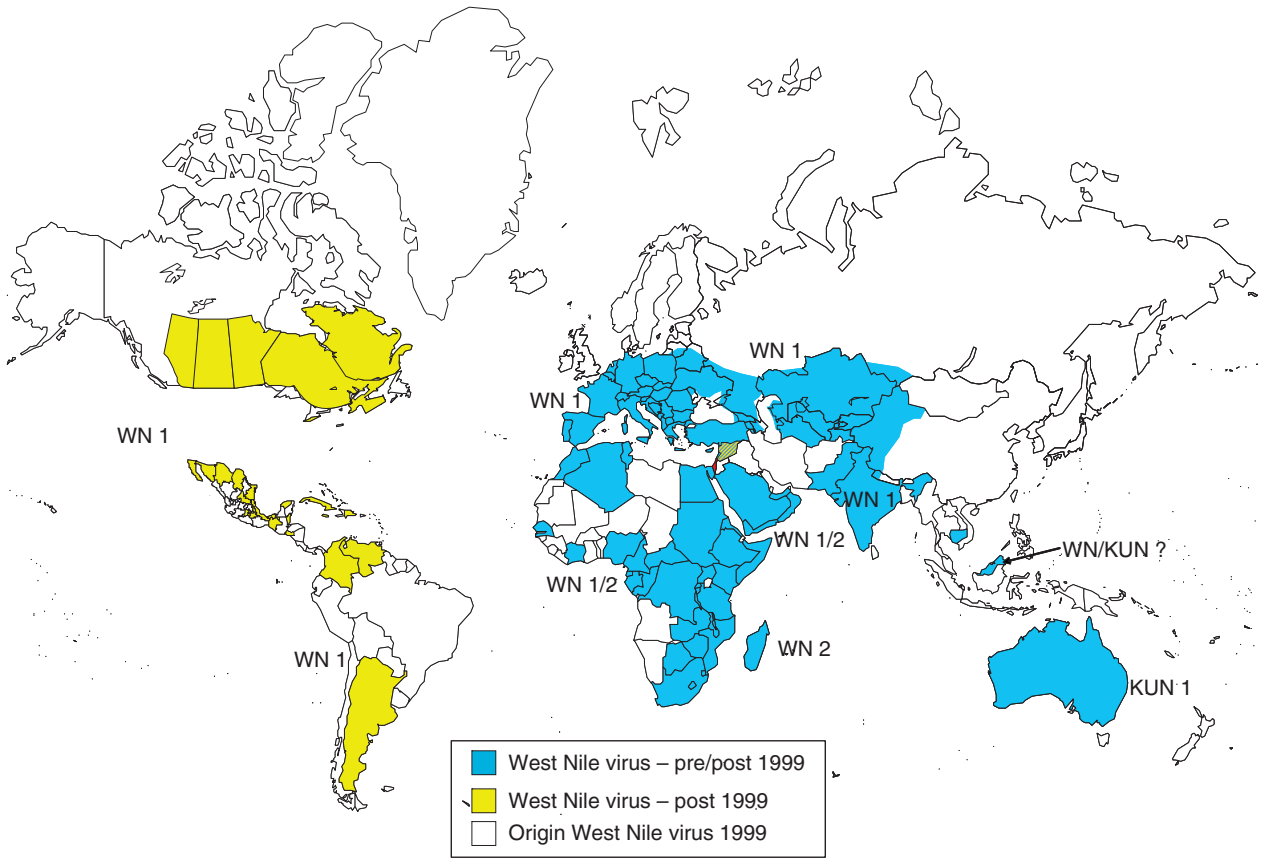

Figure 1 Global distribution of West Nile virus lineages 1 and 2. Areas in yellow have evidence of West Nile virus in the years (to 2006) following introduction of a lineage I (WN 1) virus strain in New York in 1999. This viral strain most likely originated in Israel, colored blue with yellow stripes. WN 1 viruses have been isolated from Africa, the Middle East, Europe, Russia, India, and North America. Isolations of lineage 2 WN viruses (WN 2) are found in Africa and the Middle East. Kunjin virus (KUN 1) is a subtype of lineage 1 isolated in Australia. A WN/KUN-like virus with a unique genotype (WN/KUN?) has been isolated from Sarawak, Malaysia. Modified from Scherret JH, Mackenzie JS, Hall RA, Duebel V, and Gould EA (2002) Phylogeny and molecular epidemiology of West Nile and Kunjin viruses. In: Mackenzie JS, Barrett ADT, and Duebel V (eds.) *Japanese Encephalitis and West Nile Viruses*, 379pp. Berlin, Heidelberg, and New York: Springer, with kind permission of Springer Science and Business Media.

The Virion and the Viral Genome

The West Nile virion is spherical, enveloped, approximately 50 nm in diameter, with relatively smooth surfaces and icosahedral symmetry (**Figure 4**). It contains a host-derived lipid bilayer surrounding a nucleocapsid that consists of the viral RNA complexed with multiple copies of the capsid protein. The viral genome is linear, positive-sense, single-stranded RNA, 11 029 bases in length. The 5′ noncoding region of WNV has a methylated type 1 cap (m^7GpppAmp); the 3′ noncoding region lacks a polyadenylated tail and in its place has a 5′-CU_{OH}-3′. These two regions contain conserved secondary structures critical to viral replication. The viral genome encodes three structural and seven nonstructural proteins in a single long open reading frame of 10 299 nt (nt 97–10 395), which is cleaved co- and post-translationally. The structural proteins (capsid (C), membrane (prM/M), and envelope (E)) are encoded at the 5′ end of the genome and the nonstructural proteins (NS1, NS2a, NS2b, NS3, NS4a, NS4b, and NS5) at the 3′ end. The E protein, the predominant protein of the virion, plays a major role in viral assembly, receptor binding, and membrane fusion, and is the principal target for neutralizing antibody. The NS proteins are responsible for viral RNA replication but also may function in viral assembly and in evasion of the host immune response. The putative function and nucleotide positions of the viral proteins are listed in **Table 1**.

Replication

WNV is able to replicate in a great variety of vertebrate cells. Replication is a complex process mediated in a controlled fashion through sequential interactions among viral RNA, proteins and host factors (**Figure 5**). The virion initially binds to the cell receptor and then enters via receptor-mediated endocytosis. Glycosaminoglycans have

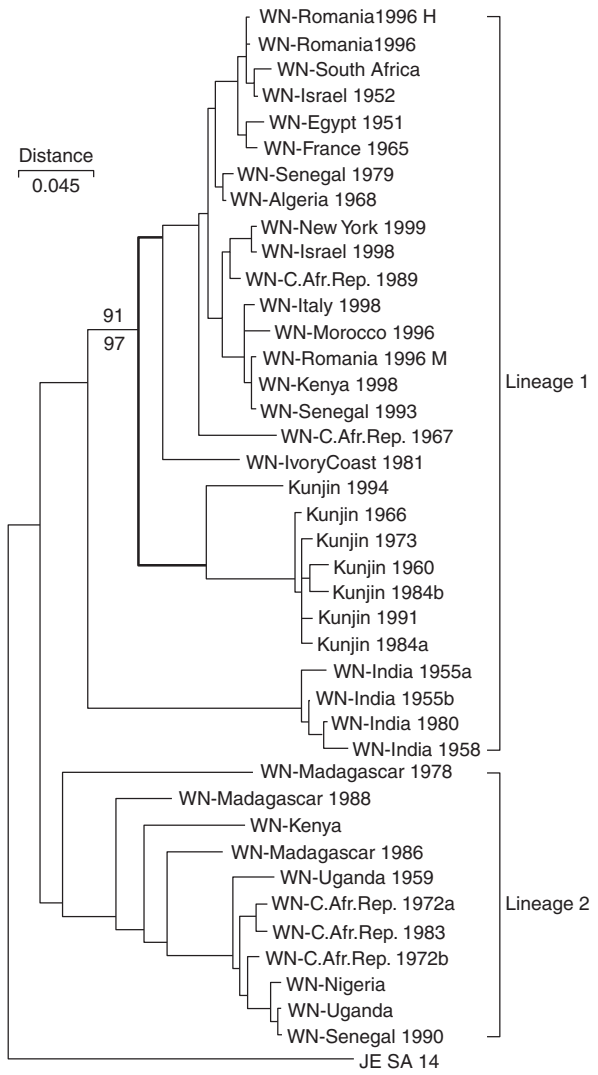

Figure 2 Phylogenetic tree based on E-glycoprotein nucleic acid sequence data (255 base pairs). The tree was constructed with the program MEGA by neighbor-joining with Kimura two-parameter distance (scale bar). Bootstrap confidence level (500 replicates) and a confidence probability value based on the standard error test were calculated using MEGA and are included on the tree (top and bottom values, respectively), illustrating support for the division between the lineage 1 WN virus group (not including the India isolates) and the KUN virus group. The best estimated length of the segment (bold line) separating these groups, in units of expected nucleotide substitutions per site, is 0.06928 and is statistically significantly positive ($P < 0.01$) by the likelihood ratio test (fastDNAml maximum likelihood program). An approximate 95% confidence interval for the true length of this segment is 0.03347, 0.10737. GenBank accession numbers can be found in Lanciotti RS, Roehrig JT, Deubel V, *et al.* (1999) Origin of the West Nile virus responsible for an outbreak of encephalitis in the northeastern United States. *Science* 286: 2333–2337, reproduced with permission.

been proposed as the putative receptors, although definitive proof is lacking. Following release of the nucleocapsid into the cytoplasm, the viral RNA is uncoated and translation proceeds, forming a single polyprotein which is cleaved into the ten viral proteins. Genomic plus-sense RNA is transcribed into complementary minus-sense RNA at the endoplasmic reticulum membranes, forming replication complexes, which in turn serve as templates for the synthesis of new plus-sense RNA. The process is asymmetric, yielding 10- to 100-fold excess plus strands. The plus-sense RNA is packaged by viral C protein to form the nucleocapsid that is enclosed in an envelope consisting of a host-derived lipid bilayer and viral prM/M and E proteins. prM is cleaved in the *trans*-Golgi network, while M remains inserted in the envelope of the virion. Mature virions are released from the infected cell by exocytosis beginning 10–12 h after infection.

Ecology

Vectors

WNV is a zoonosis maintained in an enzootic cycle, transmitted primarily between avian hosts and ornithophilic mosquito vectors (**Figure 6**). Mosquitoes of the genus *Culex* are the predominant vectors in the enzootic cycle throughout the range of the virus' distribution, although the particular species of *Culex* varies according to geographic location. In the northeast, *Culex pipiens* and *C. restuans* may be important enzootic catalysts in the spring, while the former, an urban species that reaches high densities in midsummer, also may be the critical vector to humans in the northeastern and north central US as well as in recent outbreaks in Europe and Israel. *C. quinquefasciatus*, a member of the *C. pipiens* complex, is the primary vector in the southern US and, presumably, Latin America. Another important vector in these locations is *C. nigripalpus,* while *C. tarsalis* is the predominant vector in rural areas of western states in the US. Other *Culex* spp., such as *C. univitattus* and *C. antennatus* (Europe and Africa), *C. vishnui complex* (India), and *C. annulirostris* (Australia) have been implicated in the transmission cycle.

Vector competence varies between species and within populations of individual species. The *C. pipiens* complex contains two genetically distinct forms, that is, *C. pipiens* form 'pipiens' and form 'molestus'. The two forms differ in physiology and behavior with obvious implications to their epidemiological importance. Form 'pipiens' is thought to be exclusively ornithophilic while the urban form 'molestus' will feed on mammals. The two forms have been shown to not interbreed in northern Europe, in contrast to US populations, which contain individuals with hybrid genetic signatures (*pipiens* × *molestus*). Such hybridization, which also has been noted in southern Europe, may generate bridge vectors, disposed to feed on both birds and mammals. Indeed, US populations of *C. pipiens*, as well as *C. nigripalpus* and *C. tarsalis*, have been demonstrated to shift their feeding from birds to mammals in the late summer and early fall, and therefore may act as bridge vectors to infect equid and human hosts. It is

(b) Central section of the reconstruction, showing the concentric layers of mass density. (c) WNV genome, single-stranded positive-sense RNA, approximately 11 kb in length, consisting of a 5′ untranslated region (UTR), a single long open reading frame (ORF), and a 3′ UTR. The ORF encodes three structural and seven nonstructural proteins. (a, b) Modified from Mukhopadhyay S, Kim BS, Chipman PR, Rossmann MG, and Kuhn RJ (2003) Structure of West Nile virus. *Science* 302(5643): 248, as published in Kramer LD, Li J, and Shi PY (2007) West Nile virus: Highlights of recent advances. *Lancet Neurology* 6: 171–181, with permission from Science and Elsevier.

likely that other species of bridge vectors also become involved since virus has been isolated from mosquitoes of approximately 75 species of 10 genera worldwide; but the relative importance of each species in transmission to birds or humans must take into account factors of vectorial capacity, including field infection rates and population density. Many mosquito species actually may be incidental vectors of little epidemiologic significance, but further research is required to determine their importance in the ecology and epidemiology of WNV in North America.

The mechanism(s) of WNV perpetuation over adverse seasons and years may vary by region and country, but possible mechanisms include continuous low-level virus transmission, reinitiation after reintroduction of virus by migratory birds from locations where virus is active year-round, vertical transmission to females about to enter reproductive diapause in winter, and recrudescence of low levels of virus in chronically infected birds when mosquitoes are active (**Figure 6**). Viral RNA and infectious virus have been detected in experimentally infected wild birds more than 6 weeks after inoculation. Virus

Table 1 Functions and nucleotide positions of West Nile virus proteins

Viral protein	*Function*	*Position in genome*
Structural proteins		
C	Regulation of viral replication	97–465
(Pr)M	E folding and function	(466–7421) 742–966
E	Receptor binding	967–2469
	Membrane fusion	
	Viral assembly	
Nonstructural proteins (all NS proteins are required for viral replication)		
NS1	Early replication events (interaction with NS4A essential for replication)	2470–3525

has been isolated from diapausing adult *C. pipiens* in the eastern US in the winter, from vertically infected male and female *C. univitattus* in Kenya, and from *C. quinquefasciatus* larvae in California during the summer transmission season. Vertical transmission has been demonstrated in the laboratory at rates varying with the population of mosquitoes tested.

Alternate modes of vector transmission have been observed in the laboratory and/or field. Nonviremic transmission has been demonstrated in the laboratory, with low rates of infection in co-feeding mosquitoes. This mode of transmission may expand the enzootic transmission cycle to involve mammals and birds that generally mount viremias too low to infect feeding mosquitoes. WNV has been isolated repeatedly in Russia from soft ticks (*Argasidae*), but their role in the transmission cycle is not clear. In addition, soft ticks have been demonstrated to transmit virus in the laboratory, and nonviremic transmission has been demonstrated. *Ixodidae* (hard ticks) allow the virus to pass transstadially, but are incompetent vectors. Other arthropods have been suggested as alternative vectors, including dermanyssoid mites, swallow bugs, and hippoboscid flies.

Vertebrates: Birds

Birds of more than 300 species in North America have been reported infected with WNV, as determined by virus isolation or antibody, confirming their role as the primary vertebrate in the enzootic cycle. Feeding by infected mosquitoes is the most common route of infection, but transmission to birds also has been demonstrated by direct contact, presumably via the fecal–oral route since there is significant shedding of virus, and by ingestion of infected mosquitoes or of carrion by omnivorous birds such as corvids and raptors. Experimental studies indicate that birds vary significantly in susceptibility and response to infection. The hallmark of WNV activity in North America is the significant morbidity and mortality in a wide range of species, although bird deaths also have been noted in the Middle East and recently in eastern Europe. An Egyptian strain isolated in the 1950s from a sick pigeon (*Columba livia*) is virulent in experimentally infected hooded crows (*Corvus corone*) and house sparrows (*Passer domesticus*). Corvids, especially crows, magpies, and jays, appear to be the most highly susceptible to disease, with 100% of American crows (*Corvus brachyrhynchos*) becoming sick and dying after infection with low doses of WNV. Nonetheless, corvids do not appear to be the primary amplifying hosts in the enzootic transmission cycle. In the northeastern and mid-Atlantic US, the American robin (*Turdus migratorius*) appears to be highly preferred by the predominant vector *C. pipiens*. Disproportionate numbers of mosquito blood meals are taken from robins and they have high levels of IgG antibody to WNV, indicating their importance in the enzootic cycle. In the laboratory, robins have average host competence determined by susceptibility, number of days infectious, and level of viremia or mean infectiousness. High levels of WNV IgG have been detected in other birds as well, including cardinals and wrens, and in some locations, house sparrows.

Vertebrates: Other

Thirty species of mammals and occasionally other vertebrates including reptiles and amphibians have been found

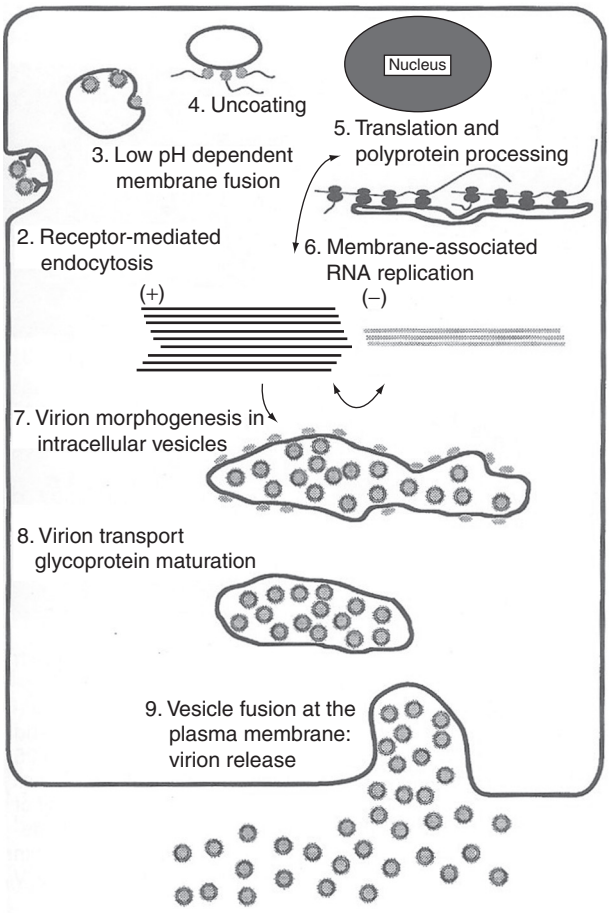

Figure 5 Flavivirus replication cycle. Highlights of the flaviviral replication cycle are diagrammed. Reproduced from Rice CM (1996) *Flaviviridae*: The viruses and their replication. In: Fields BN, Knipe DM, Howley PM, *et al*. (eds.) *Fields Virology*, 3rd edn., pp. 931–959. Philadelphia: Lippincott-Raven Publishers, with permission from Lippincott Williams and Wilkins.

infected with WNV. Their role in the transmission cycle is less significant than that of birds because of their generally low levels of viremia, but some small mammals, such as rabbits and chipmunks, have been demonstrated in the laboratory to mount sufficiently high levels of virus in the blood to infect a small proportion of feeding *Culex* spp. mosquitoes. In the US and Mexico, farmed alligators raised at high temperatures in crowded conditions demonstrate significant mortality and mount high viremias. Transmission appears to occur directly between alligators, as well as through ingestion of uncooked infected horse meat. Enzootics in equines have occurred in the US, France, Italy, Morocco, and Israel. Unvaccinated equines develop infections ranging from asymptomatic to encephalitic disease, and demonstrate a case–fatality rate of approximately 25%. Because of their low viremias, they likely are incidental hosts in the transmission cycle.

Low levels of WNV antibody in domestic pets have been detected in serosurveys in the US and in the Highveld region of South Africa. In the laboratory, dogs and cats are readily infected with WNV, but dogs do not develop detectable viremia and peak titers in cats are too low to infect most mosquitoes. Cats also may become infected by the oral route following feeding on dead infected mice. Sera from wild-caught vertebrates after intensive activity in 2003 in the US also demonstrated high levels of infection in raccoons, Virginia opossums, fox squirrels, and eastern gray squirrels. It is unclear how much morbidity and mortality is associated with WNV in wild mammals, but occasional cases of overt disease have been reported. Some small mammals, such as chipmunks and rabbits, have been shown experimentally to mount viremias sufficient to infect mosquitoes.

Vertebrate Pathogenesis

Infected mosquitoes expectorate virus with their saliva mostly intradermally but also intravascularly while probing and feeding, and their salivary secretions contain potent pharmacologic compounds that affect viral pathogenesis. The initial site of viral replication in the vertebrate is thought to be subdural Langerhans' dendritic cells at the site of inoculation. Activated dendritic cells migrate to draining lymph nodes where the virus replicates further, antigen processing begins, and an early immune response may become evident. Virus enters the blood by way of the efferent lymphatics and thoracic duct, resulting in a viremia that carries the virus to the visceral organs of the body, and possibly facilitates virus crossing the blood–brain barrier. However, the mechanism for the latter is unknown and may occur via infected inflammatory cells, retrograde transport along peripheral nerve axons, replication in epithelial cells, or by another route. Neurons, the main target cell in the central nervous system, suffer pathology, as do bystander nerve cells. In addition, there is immune-mediated tissue damage.

Factors such as age, immune status, and genetic susceptibility of the host, strain of virus, dose of inoculum, and route of infection, affect pathogenesis of WNV. In the mouse, variations in a single gene, Flv, on chromosome 5, determine the rodent's susceptibility to WN disease, but not infection. Susceptibility has been mapped to the gene encoding the L1 isoform of the interferon-inducible, antiviral effector enzyme 2′–5′-oligoadenylate synthetase. An intact immune system is critical to prevention of disease, and both humoral and cellular factors play a role in protection against disease. Neutralizing antibody is the principal means of viral clearance. Interferon-dependent innate immune responses are essential in limiting infection of WNV, as is the adaptive immune response. Complement, dendritic cells and chemokines probably also play roles in viral clearance. The mechanism by which infection is cleared from neurons appears to involve CD8+ T cells in

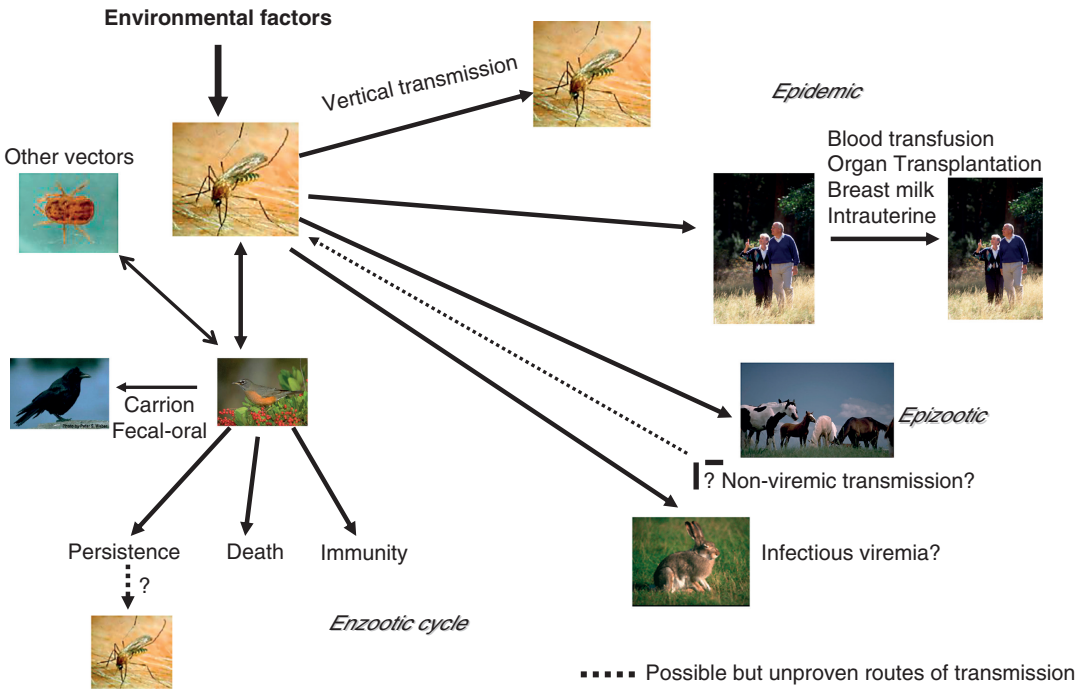

Figure 6 West Nile virus transmission cycle. The enzootic cycle is illustrated, as well as epidemic and epizootic hosts. Solid arrows indicate confirmed transmission pathways; dotted lines proposed pathways that have not been confirmed in nature.

the perforin-dependent class I major histocompatibility complex (MHC)-restricted system. Persistence of virus has been noted to occur in some vertebrates following natural and experimental infection, even in the presence of neutralizing antibody. Hamsters shed WNV in their urine for ≥ 8 months and virus can be isolated from their brains as long as 53 days after infection.

Clinical Disease

The range of symptoms associated with WNV infection extends from uncomplicated febrile illness to meningitis, neuropathies, muscle weakness, paralysis, and encephalitis. Symptoms generally become apparent 2–14 days after infection by mosquito bite, but 80% of infected individuals are asymptomatic. The majority of symptomatic patients present with flu-like symptoms, termed WN fever, which in the US has been associated with substantial morbidity. The duration of symptoms may be from days to months, and the patient may require hospitalization. WNND includes meningitis, encephalitis, and acute flaccid paralysis (AFP). From 1999 to 2007, 27 083 cases of WN disease were reported in the US, of which 57.3% were WN fever and 40.3% were WNND resulting in 1054 fatalities (3.9% of all, 9.7% of WNND) (**Table 2**). Given the proportion of symptomatic cases (~20%), approximately 135 415 individuals were infected with WNV over the 8-year period, and 8.1% of all infections were WNND. Males were more commonly infected than were females. Movement disorders, that is, dyskinesias, frequently characterized as parkinsonism are common. The constellation of fever, headache, and signs of meningeal irritation, cannot be easily discriminated from other flaviviral encephalitides. Patients with AFP experience loss of spinal anterior horn cells and have accompanying asymmetric weakness. Risk factors for WNND include age, diabetes, and possibly a history of hypertension or cardiovascular disease. The median age of WNND cases in the US since 1999 is 57 years (46 years for WNF), but there have been reports of WNND in children and AFP in young adults. Infection may persist in the central nervous system of immunologically compromised patients, leading to extended neurologic illness and sequelae. The mortality rate following WN encephalitis is greater than following WN meningitis. Immunosuppression, chronic renal disease, and hepatitis C infection have been recognized as risk factors for death after adjustment for age. Rare cases of hemorrhagic WNV disease have been noted.

The vast majority of human cases are transmitted by the bite of an infected mosquito. However, human-to-human transmission after blood transfusions, organ transplantation, and through mothers' milk have occurred in the US and there has been one instance of intrauterine transplacental transmission. High-throughput nucleic acid detection assays were developed and implemented by blood banks in response to transfusion transmission in order to protect the blood supply.

Table 2 Human West Nile virus disease cases, United States, 1999–2005

Year	*Total cases*	*WNND cases (% of total)*	*WNF cases (% of total)*	*Other clinical/unspecified*	*Fatalities (% of WNND cases)*
1999	62	59	3	0	7
2000	21	19	2	0	2
2001	66	64	2	0	9
2002	4 156	2 946	1 160	50	284

WNND, West Nile neurologic disease; WNF, West Nile fever.
Reported to CDC, as of 06 November 2007.

Diagnostics

Human

Studies of infected blood donors indicated the presence of WNV IgM and IgA at the earliest on day 3 and in all cases by day 8–9 after RNA was detected; IgG antibody appeared about 1 day later (**Figure 7**). The detection of IgM antibody in the cerebrospinal fluid (CSF) by a monoclonal antibody (MAb) capture enzyme-linked immunosorbent assay (MAC ELISA) in conjunction with evidence of neurologic symptoms has been accepted as diagnostic of WNV disease. Presence of IgM antibody in the serum alone is strongly suggestive of recent infection but not definitive due to persistence for at least 16 months (199 days in the CSF) in patients with WNND, and to some cross-reactivity with antibody to other flaviviruses. The plaque reduction neutralization test (PRNT) in Vero cell culture remains the gold standard in diagnosis of flavivirus infections because of the extensive cross-reactions complicating diagnosis. A fourfold rise in neutralizing antibody titer between paired acute-phase and convalescent-phase sera confirms WNV infection, as does a fourfold or greater titer to WNV compared to related flaviviruses. However, interpretation is complicated in individuals who have had prior infection with another flavivirus. Microsphere immuno assay (MIA) using recombinant E protein has equivalent sensitivity to ELISA. In primary flavivirus infection, the specificity of the MIA procedure is high (>90%) compared to PRNT. However, as with PRNTs, the interpretation of WNV-E MIA is confounded when WNV is a secondary flavivirus infection. Sera from dengue (flavivirus) patients are highly likely to be positive in MIA procedures using recombinant WN E protein. Addition of WNV NS5 to a multiplex test panel increases specificity, since sera from patients with other past flavivirus infections are likely to be negative to WNV NS5 but reactive to WNV E. Serologic assays are more sensitive than detection of viral nucleic acid by reverse transcription-polymerase chain reaction (RT-PCR) once symptoms are evident because of the rapid clearance of virus by most individuals; however, detection of viral RNA is confirmatory.

Clinical findings also aid diagnosis. Neurologic symptoms indicate neuroinvasive disease. Electrophysiologic tests and magnetic resonance imaging (MRI) may be useful in cases of acute flaccid paralysis. Elevated lymphocyte counts and protein levels may be present in CSF during WNV infection. Epidemiological data also may be critical for diagnostic consideration because other flavivirus infections cause similar symptoms.

Surveillance Specimens

Submission of dead birds, particularly American crows, has provided an excellent sentinel system for WNV activity in the US, but depends upon participation by the public. In addition, over time this may not remain a reliable indicator of virus activity if selection for resistance to disease occurs. Tissues or swabs from dead birds and pooled mosquitoes are tested by real-time RT-PCR for viral nucleic acid, by cell culture procedures that detect live virus followed by confirmation using specific assays, and/or by procedures that detect viral antigen. High-throughput virus-specific molecular assays, such as real-time RT-PCR, have been developed to accommodate testing of large numbers of specimens in a timely manner.Rapid assays utilizing dip sticks to detect viral antigen also have been adopted for surveillance, but have low sensitivity. Detection of antibody in sera of live sentinel captive birds or wild-caught birds using an indirect or a competitive blocking ELISA, with confirmation by PRNT, generally has proven less useful as an early warning indicator of viral activity.

Prevention and Control

Vaccines and Therapeutics

Currently, the only available treatment for disease caused by WNV is supportive, given that no therapeutic

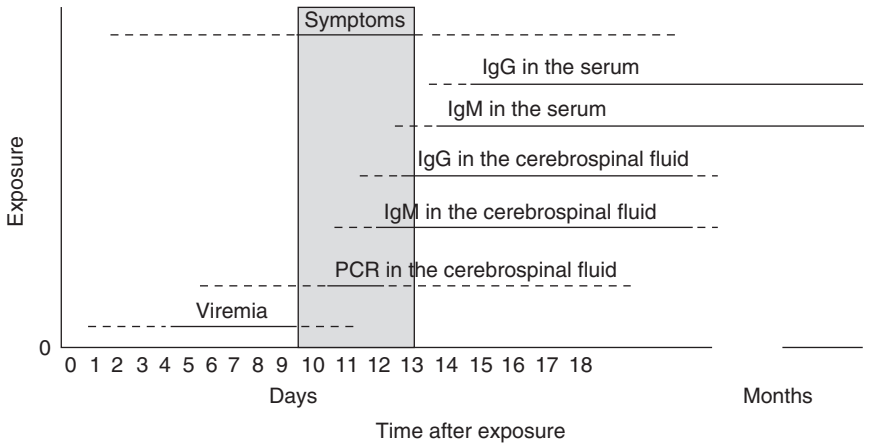

Figure 7 Schematic of virologic and serologic tests in West Nile virus encephalitis. Solid lines represent the more common results; broken lines represent reported ranges. The shaded box is an example of a typical patient. Reproduced from Gea-Banacloche J, Johnson RT, Bagic A, Butman JA, Murray PR, and Agrawal AG (2004) West Nile virus: Pathogenesis and therapeutic options. *Annals of Internal Medicine* 140: 545–553, with permission from American College of Physicians.

treatment has shown consistent clinical efficacy. Therapeutic interventions include passive administration of high-titer immune immunoglobulin. MAb, in particular humanized MAb against WNV E protein, also has shown some benefit. Interferon offers promise based on animal models but may not be helpful in treating the late-stage central nervous system disease. Finally, antiviral therapy using small sequence-specific nucleic-acid-based molecules to suppress WNV replication in tissue culture is being evaluated but the timing and high dose required remain issues of concern. Targets of intervention include viral RNA polymerase, RNA helicase, or other viral replication enzymes. WNV replicon-based high-throughput screening assays have been developed to aid in discovery of compounds with potential antiviral activity.

Advances also have been made in development and implementation of effective vaccines. Protection has been demonstrated in equids following immunization with inactivated cell culture-derived virus (Ft. Dodge). Recombinant canarypox virus containing the prM and E genes of WNV also has been licensed for use in equids. Two recombinant live virus vaccines are in clinical trial in humans. One uses a yellow fever 17D strain infectious clone, with the original yellow fever virus prM and E genes replaced by attenuated WNV genes (Acambis' Chimerivax-WN), and another uses attenuated dengue virus 4 with deletions in the 3′ end as the backbone (NIH/Macrogenics). Both live, attenuated and chimeric vaccines have the advantage of eliciting humoral and cellular responses in the host after a single dose. Other approaches include DNA vaccines that encode prM, E, or C; subunit vaccines of purified recombinant prM and E; and cross-reactive flaviviruses or WNV variants.

Public Health Measures

Reduction of WNV transmission currently relies on reduction of mosquito populations or minimizing contact between vectors and humans. Mosquito control agencies in the US have undertaken extensive larviciding to kill immature stages of mosquito vectors in the aquatic environment. Source reduction, that is, removal of standing water, also has proven helpful. Personal protection measures, for example, wearing loose clothing, use of repellents, particularly 'DEET' (*N*,*N*-diethyl-m-toluamide or *N*,*N*-diethly-3-methylbenamide), or use of window screens, reduce direct contact with mosquitoes. Community action groups have worked to increase awareness and educate the public.

Summary

The introduction of WNV to the US and its subsequent spread and successful establishment in the Western Hemisphere alerted the world to the impact of globalization on pathogen dissemination. The number of WNND cases in 2002 and 2003 represent the largest outbreak of neurologic diseases in North America. Future research undoubtedly will address development of efficacious therapeutics, effective vaccines, novel methods to control mosquitoes, and accurate risk prediction. Each of these is dependent upon solid basic research on WNV ecology, pathogenesis, and immunology.

White Spot Syndrome Virus

J-H Leu, J-M Tsai, and C-F Lo, National Taiwan University, Taipei, Republic of China

© 2008 Elsevier Ltd. All rights reserved.

Glossary

***In situ* hybridization (ISH)** A technique that uses a labeled complementary DNA or RNA probe to hybridize and detect a specific DNA or RNA sequence in a section of tissue (*in situ*).

Microarray A DNA microarray is a collection of microscopic dsDNA or oligonucleotide spots that are deposited on a solid glass slide at high density. Each spot commonly represents a single gene. DNA microarrays use DNA–DNA or DNA–RNA hybridization to perform simultaneous large-scale analyses of the expression levels of the corresponding genes.

RNAi (RNA interference) RNAi refers to the introduction of homologous double-stranded RNA to specifically interfere with the target gene's expression in the cells/organisms. It was originally discovered in *C. elegans*, and is now widely used in many organisms for null mutation. Recent studies suggest that RNAi can be applied in shrimp as well through intramuscular injection of dsRNA.

Introduction

White spot disease (WSD) is a highly contagious viral disease of penaeid shrimp. Its onset is rapid, and high levels of mortality can result within just a few days. Following the first outbreak of WSD in China and Taiwan in 1992–93, this viral disease spread quickly to other shrimp-farming areas, including Japan (1993), Thailand (1993), the United States (1995), Central and South America (1999), France (2002), and Iran (2002). Nowadays, WSD is considered endemic in almost all shrimp-producing countries in Asia and the Americas, causing serious economic damage to the shrimp culture industry. The causative agent of WSD is white spot syndrome virus (WSSV), which is a large (80–120 × 250–380 nm), non-occluded, rod-shaped to elliptical, double-stranded (ds) DNA virus. The virus has a remarkably broad host range among crustaceans, including many species of shrimp, crayfish, crab, and lobster. WSSV replication and virion assembly occur in the hypertrophied nuclei of infected cells without the production of occlusion bodies. The WSSV virion consists of a rod-shaped nucleocapsid surrounded by a trilaminar envelope and a unique, tail-like extension at one end. The virions contain a circular,

supercoiled, dsDNA genome of about 300 kilobase pairs (kbp). Complete genome sequence analyses have shown that most of the WSSV open reading frames (ORFs) encode proteins bearing no homology to known proteins, while some identifiable genes are more homologous to eukaryotic genes than to viral genes. Based on these genetic analyses and on its unique morphological features, WSSV has been classified as the sole member of a new virus family.

Taxonomy

After its initial discovery, WSSV was classified as the genus *nonoccluded Baculovirus* (*NOB*) of the subfamily *Nudibaculovirinae* of family *Baculoviridae*. However, based on its unique morphological features, on its genomic structure and composition, and on phylogenetic analyses, *White spot syndrome virus 1* was reassigned by the International Committee on Taxonomy of Viruses in 2004 as the type species of the genus *Whispovirus* and the sole member within the new virus family *Nimaviridae*. The family name refers to the thread-like, polar extension on the virus particle (*nima* is Latin for 'thread'). Today, there is still only a single species within the genus *Whispovirus*. However, various geographical isolates with genotypic variability (variants) have been identified within this species. Other names that have been used in the literature for WSSV include: hypodermal and hematopoietic necrosis baculovirus (HHNBV), rod-shaped nuclear virus of *Penaeus japonicus* (RV-PJ), systemic ectodermal and mesodermal baculovirus (SEMBV), and white spot baculovirus (WSBV).

Transmission, Host Range, and Epidemiology Studies of WSSV

WSSV is contagious and highly virulent in penaeid shrimp. In cultured shrimp, WSSV infection can cause a cumulative mortality of up to 100% within 3–10 days of the first signs of disease. WSSV can be transmitted horizontally, either *per os* when the shrimp feed on diseased individuals, contaminated food or infected carcasses, or else through exposure to virus particles in the water, in which case the route of infection is primarily through the gills or other body surfaces. The virus is also transmitted vertically from brooder to offspring. However, transmission is not transovarial because the virus appears to attack only young developing oocytes, which die before reaching maturation. It is therefore more likely that vertical transmission is caused by contamination of the egg mass. Penaeid shrimp are highly susceptible to WSSV. Although there is evidence of resistance during the larval and early (younger than PL6) postlarval stages, WSSV can cause disease in shrimp at any growth stage.

WSSV has a remarkably broad host range. Almost every species of penaeid shrimp is susceptible to WSSV infection. Moreover, the virus can infect other marine, brackish, and freshwater crustaceans, including crayfish, crabs, and spiny lobsters. However, in contrast to penaeid shrimp, infection is often not lethal in these species, and consequently they may serve as reservoirs and carriers of the virus. Furthermore, at least one insect, the shore fly (a member of the family Ephyridae), as well as copepods collected from WSSV-affected farms, have been diagnosed as WSSV-positive by PCR, suggesting that they are also possible reservoir hosts.

In epidemiological studies of WSSV, variations in the number of the 54 bp tandem repeat located between the *rr1* and *rr2* genes (see the section titled 'Identification through homology comparison') have been used as a strain-specific, genetic marker. The number of repeats varies greatly when infected shrimps are collected from different ponds or from the same ponds at different times, but in almost every outbreak of WSD, shrimps from the same pond usually have the same number of repeats. This suggests that in each pond, a single WSSV isolate is the causative agent. High variations in the number of 54 bp repeats have been reported in strains of WSSV from Thailand, India, and Vietnam. In Vietnam, a particular repeat pattern was observed in shrimps from outbreak ponds, but no repeat pattern was found to be useful as a prediction of pathogenicity or geographical origin in any of these different strains. On the other hand, cultured shrimps and wild crustaceans from the same WSD outbreak pond had different 54 bp repeat patterns, suggesting that the wild crustaceans may not have been responsible for infecting the cultured shrimp. However, this interpretation has been questioned by a recent study showing that the number of the 54 bp repeats as well as the pathogenicity changed when a given WSSV isolate was passaged through different crustacean hosts. This study further implies that the variations in repeat number could result from host selection rather than geographical isolation.

Clinical Features and Pathology

The most commonly observed clinical sign of WSD in shrimp is white spots in the exoskeleton and epidermis. These may range in size from minute spots to disks several millimeters in diameter which may coalesce into larger plates. The spots may result from abnormal deposits of calcium salts by the cuticular epidermis or result from disruption to the transfer of exudates from the epithelial cells to the cuticle. Infected animals are lethargic, reduce their food consumption, and display a reddish to pink body discoloration due to expansion of cuticular chromatophores. Moribund shrimp exhibit systemic destruction of

target tissues with many infected cells showing homogeneous hypertrophied nuclei. At advanced stages of infection, numerous virus particles are released into the hemolymph from the lesions, causing a general viremia.

It should be noted that although the white spots are a typical and characteristic clinical sign of WSD, white spots on the carapace of shrimp can also be caused by other environmental stress factors, such as high alkalinity or a bacterial shell disease. Conversely, moribund shrimp with WSD may have few, if any, white spots.

To date, no species of penaeid shrimp is known to show significant resistance to WSD.

Histopathology

The prime targets for WSSV replication are tissues of ectodermal (cuticular epidermis, fore- and hindgut, gills, and nervous tissue) and mesodermal (lymphoid organ, antennal gland, connective tissue, and hematopoietic tissue) origin. Tissues of endodermal origin (hepatopancreas and midgut) are not affected by the virus. Histopathological observation reveals similar cellular changes upon WSSV infection in all target tissues. In the early stage of infection, affected cells display nuclear hypertrophy (**Figure 1**), nucleoli dissolution, and chromatin margination, and the central area changes into a homogeneous eosinophilic region. The infected cells then proceed to develop an intranuclear eosinophilic Cowdry A-type inclusion, which subsequently becomes a light basophilic, denser inclusion separated by a transparent zone from the marginated chromatin. During this time, the cytoplasm becomes less dense and more lucent. In the late stage of infection, the nuclear membrane is disrupted, causing the intranuclear transparent zone to fuse with the lucent cytoplasm. At the end of cellular degeneration, the nucleus or whole cell disintegrates, leading to loss of cellular architecture. In moribund shrimp, most tissues and organs are heavily infected with the virus, and they exhibit severe multifocal necrosis.

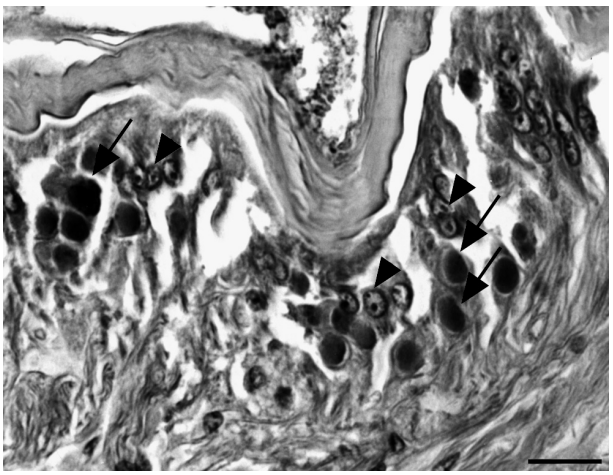

Figure 1 Hematoxylin and eosin (HE) staining of tissue section from *Penaeus monodon* cuticular epithelium of eyestalk infected with WSSV. Degenerated cells characterized by hypertrophied nuclei (black arrows) are readily seen. The cells with normal nuclei are also indicated with arrowheads. Scale = 20 μm.

Temporal studies coupled with *in situ* hybridization (**Figure 2**) have shown that the first WSSV-positive signals are detected in the stomach, gills, cuticular epidermis, and connective tissue of the hepatopancreas. At later stages of infection, the lymphoid organ, antennal gland, muscle tissue, hematopoietic tissue, heart, midgut, and hindgut also become positive. As infection proceeds, the stomach, gill, hematopoietic tissue, lymphoid organ, antennal gland, and cuticular epidermis become heavily infected with WSSV, which leads to serious damage and necrosis (and/or apoptotsis; see the section titled 'Viral–host relationships').

Viral Morphology and Morphogenesis

The WSSV virion is a nonoccluded particle with a trilaminar envelope. It is elliptical to bacilliform (olive-like) in shape and measures about 270 × 120 nm. A long, tail-like projection is often seen extending from the narrow end of the purified virion (**Figure 3**(**a**)). The cylindrical, rod-shaped nucleocapsid is about 300 × 65 nm, which is longer than the intact virion. The nucleocapsid displays a very distinctive pattern consisting of a stacked series of rings (about 16 in total) that run perpendicular to the longitudinal axis of the capsid. The thickness of these rings is quite constant, at about 20 nm. Each ring consists of two rows of 12–14 globular subunits, each approximately 10 nm in diameter (**Figure 3**(**b**)).

The entire WSSV replication cycle takes place in the nucleus and, in an acutely infected shrimp, can be completed within 24 h post infection. Initial signs of WSSV replication in the nucleus include nuclear hypertrophy and chromatin margination. Viral morphogenesis begins with *de novo* formation of the viral envelope, which can be seen at first as fibrillar fragments in the nucleoplasm. As infection progresses, these fragments form into the membranous and/or vesicular precursors of the viral envelope. The development of nucleocapsids begins with the formation of long empty tubules (**Figure 4**(**a**)) which have a diameter similar to that of empty nucleocapsids and a segmentation similar to that of nucleocapsids. They can exist individually or may be laterally aligned in groups of two or three to form a larger structure. The assembled tubules break into fragments of 12–14 rings to form empty naked capsids (**Figure 4**(**b**)) which are then surrounded by envelopes, leaving an opening at one end. Nucleoproteins, which have a filamentous appearance, enter the capsid through this open end, while

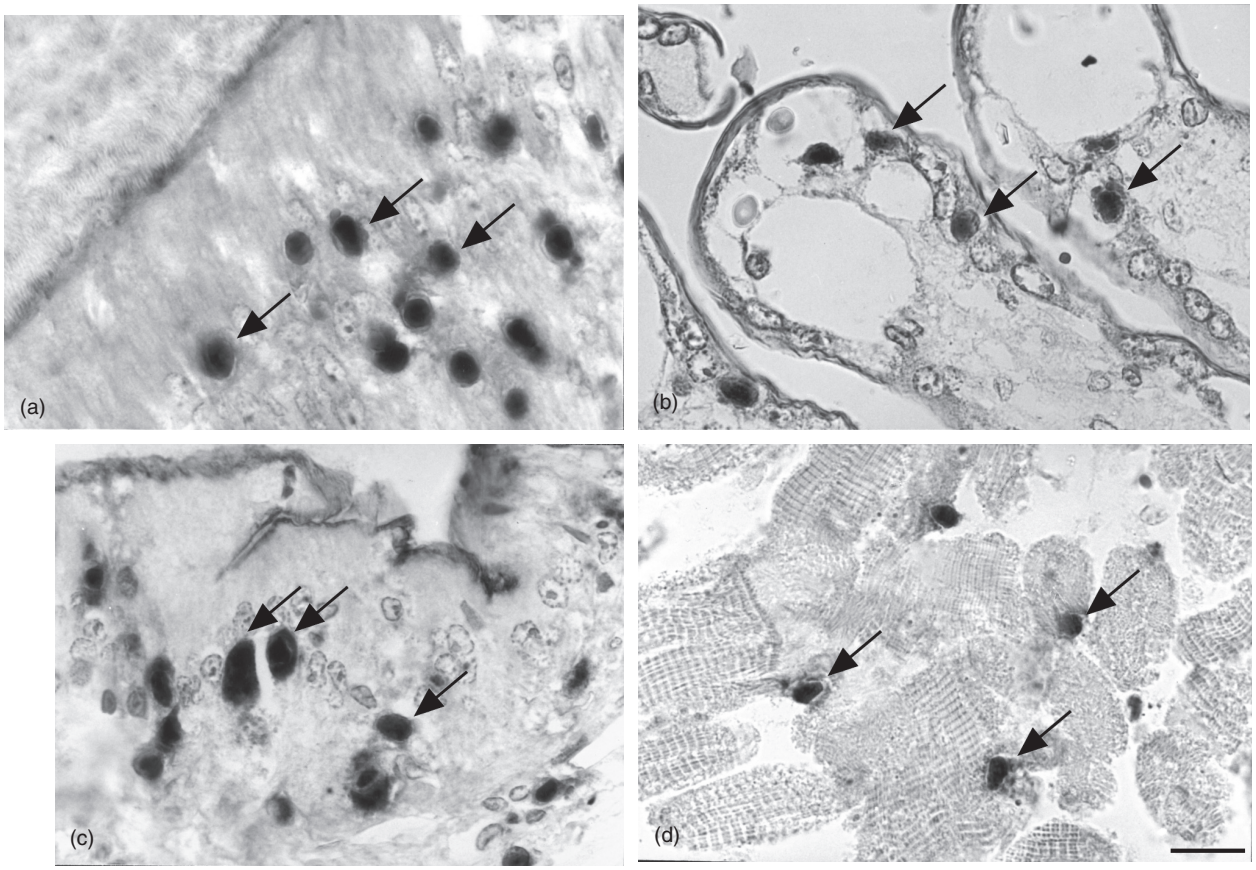

Figure 2 *In situ* hybridization analysis of WSSV positive cells (arrows) in (a) the integument, (b) the gill, (c) the stomach, and (d) the heart from experimentally infected *Penaeus monodon* at 60 hpi. The infected cells shown here in the heart are connective tissue cell; muscle cells are not usually targeted by WSSV. Scale = 20 μm.

simultaneously increasing the diameter of the virion. Finally, the open end of the nucleocapsid is closed, and the envelope narrows at the open end to form the apical tail of the mature virion, which has now obtained its characteristic olive-like shape.

Virion Structure and Composition

WSSV virions have a complex SDS-PAGE protein profile (**Figure 5(a)**). Early structural protein studies used SDS-PAGE coupled with Western blot analyses and/or N-terminal sequencing of proteins to identify at least six structural proteins, including VP35, VP28, VP26, VP24, VP19, and VP15. More recent studies have used mass spectrometry to analyze the protein profiles of purified WSSV virions separated by SDS-PAGE and 2-D electrophoresis, and more than 40 structural proteins have now been identified. The major structural proteins are VP664, VP28, VP26, VP24, VP19, and VP15 (**Figures 5** and **6**). A biochemical fractionation study using differential concentrations of salt and detergent has tentatively classified the WSSV structural proteins into envelope, tegument, and capsid proteins. VP15 is a basic capsid protein with *in vitro* DNA-binding activity, and it has high homology to the lysine- and arginine-rich DNA-binding proteins of the insect baculoviruses. This protein is therefore thought to be responsible for packing the WSSV DNA into the nucleocapsid. VP26, a tegument protein, can interact with actin, but the importance of this interaction remains unknown. VP19, VP24, and VP28 are envelope proteins, and an *in vitro* physical interaction between VP24 and VP28 has been reported. VP664, the major capsid protein, takes its name from its calculated molecular weight of 664 kDa, and it is not only the largest protein encoded by the WSSV genome, but also the largest viral structural protein ever found. This protein is encoded by the intron-less giant ORF (*wssv419*) of 18234 nt. Immunoelectron microscopy of purified virions has shown that VP664 forms the globular subunits that are visible in the nucleocapsid ring structures (**Figure 6**). In addition to VP15 and VP664, the capsid contains at least four other minor proteins: VP160A (WSSV344), VP160B (WSSV94), VP60B (WSSV474), and VP51C (WSSV364) (**Figure 5**).

A number of viruses use the Arg-Gly-Asp (RGD) motif to bind to cellular integrins during infection and

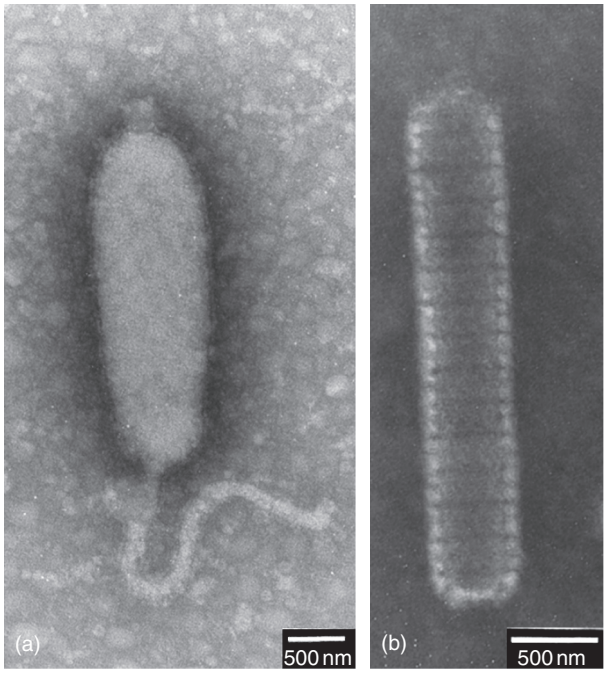

Figure 3 Morphology of the WSSV virions. (a) Intact WSSV virion showing the tail-like extension on one end. (b) A WSSV nucleocapsid showing the stacked ring structures, which are made up of two rows of globular subunits.

this cell attachment site signature can be identified in at least six WSSV structural proteins. It has been shown that one of these six structural proteins, VP110 (WSV035), can attach to shrimp host cells, and that this adhesion can be blocked by synthetic RGDT peptides, suggesting that the RGD motif in VP110 may play a role in WSSV infection. VP28 may also bind to host cells even though it lacks the RGD motif, and virus neutralization tests originally suggested that VP28 was critical for systemic WSSV infection. However, recent studies have shown that the observed phenomenon was, in fact, a nonspecific inhibitory effect of rabbit serum. Thus, to date, although SDS-PAGE indicates that VP28 is the most abundant virion protein, its role remains elusive. In addition to VP28, virus neutralization tests have been used to identify other structural proteins in the envelope and determine their role in WSSV infection. However, considering what is now known for VP28, the results of neutralization tests should be interpreted with care.

None of the five small major WSSV structural proteins (VP28, VP26, VP24, VP19, and VP15) appears to be glycosylated. However, increased migration in SDS-PAGE after N-linked glycosidase F treatment of structural protein VP180 (encoded by *wsv001*) suggests that this large collagen-like protein is N-glycosylated. This is the first reported evidence of an intact collagen gene in a virus genome.

WSSV Genome Structure

The WSSV genome is a large ds circular DNA of about 300 kbp. The complete genome sequences of three isolates originating from China (WSSV-CN), Taiwan (WSSV-TW), and Thailand (WSSV-TH) indicated sizes of 305, 307, and 297 kbp, respectively. Genetic variations among these isolates include two major polymorphic loci

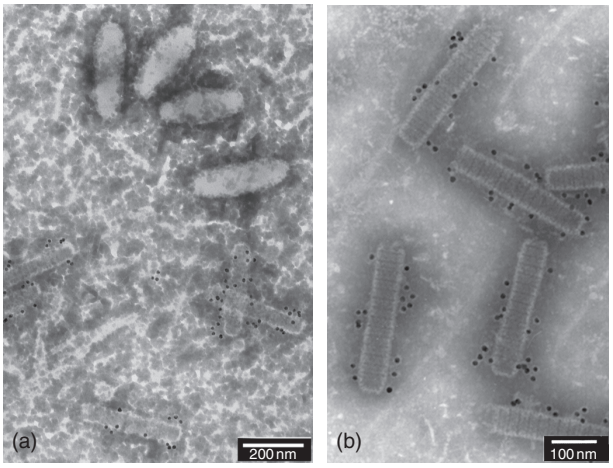

Figure 6 Immunoelectron microscopy analysis of purified WSSV virions detected with VP664 antibody followed by gold-labeled secondary antibody. (a) The VP664 antibody specifically binds to the nucleocapsid and not to the viral envelope. (b) Most of the gold particles are localized at the perimeter of the nucleocapsid.

(a 13 kbp deletion in WSSV-TH and a variable region prone to recombination), a transposase sequence that was only present in WSSV-TW, and variation in the number of repeats and single nucleotide mutations. Not including the two major polymorphic loci and the transposase sequence, these three isolates share an overall nucleotide sequence identity of 99.32%. It has been shown that differences in the major polymorphic 13 kbp deletion locus are related to differences in virulence of WSSV isolates.

The WSSV genome has a total G + C content of 41% uniformly distributed over the genome. Although most WSSV genome sequences are unique, 3% of the genome consists of highly repetitive sequences, which are organized into nine homologous regions (hrs). These are distributed throughout the genome, and are located largely in intergenic regions. The presence of hrs is a feature of many baculovirus genomes. Baculovirus hrs function as enhancers of early gene transcription and as initiation sites for DNA replication. They have also been implicated as sites of DNA recombination. It is likely that WSSV hrs will be shown to have similar functions.

A total of 532 putative ORFs consisting of a minimum of 60 codons have been identified by sequence analysis of the WSSV-TW isolate. Of these, 140 ORFs have a potential downstream polyadenylation site (AATAAA). The size of proteins encoded by these predicted ORFs ranges from 60 to 6077 amino acids. Only 30% of the predicted ORFs encode proteins homologous to any other known proteins or motifs. As about 40 structural proteins have been identified, approximately 8% of the ORFs encode structural proteins. Some of the predicted ORFs encode proteins that share significant similarities (40% or even higher) to each other and can therefore be classified into the same gene family. There are ten putative gene families in the WSSV genome, and it is possible that these families arose from gene duplication.

WSSV Genes

Identification through Homology Comparison

The WSSV genome contains several genes that can be identified unambiguously through homology searches. These genes are involved in nucleotide metabolism and DNA replication, and encode *thymidylate synthase*, *dUTPase*, *ribonucleotide reductases* (*rr1* and *rr2*; two separate ORFs encoding the two subunits), chimeric *thymidylate/thymidine kinase* (*TK-TMK*), and *DNA polymerase*. The chimeric *thymidylate/thymidine kinase* gene is a unique feature of WSSV, as these genes in other large DNA viruses are encoded in separate ORFs. The enzymatic activities of dUTPase, ribonucleotide reductase, and TK/TMK have been demonstrated by using purified recombinant proteins.

Some proteins from predicted ORFs show weak similarity to known proteins, including nonspecific nuclease (WSV191), TATA-box binding protein (TBP; WSV303), CREB-binding protein (CBP; WSV100), and helicase (WSV447). The activity of the nonspecific nuclease has been demonstrated using a purified recombinant protein produced in *Escherichia coli*.

Some proteins contain well-defined domains or motifs, and therefore their possible functions can be inferred. Two protein kinases, PK1 (WSSV482) and PK2 (ORF61), have been identified because they each contain the catalytic domain of serine/threonine protein kinase. Two proteins containing the EF-hand, calcium-binding motif have also been identified (WSV079 and WSV427; WSV427 is a latency-related gene), suggesting that WSSV might modulate calcium levels in infected cells. Four proteins with RING-H2 finger motifs have been annotated (WSV199, WSV222, WSV249, and WSV403). This motif has been implicated in ubiquitin-conjugating enzyme (E2)-dependent ubiquitination; many proteins containing a RING finger play a key role in the ubiquitination pathway. Ubiquitination activity has been demonstrated for WSV222 and WSV249, and their interacting host proteins have been identified using yeast-two hybrid screening. Some proteins contain conserved zinc finger or leucine zipper motifs. These motifs have been shown to be involved in DNA-protein interactions and in regulation of transcriptional activation. Of these, *wssv126* is one of three immediate early genes that have been identified to date.

Identification through Functional Studies

As most WSSV gene products show no significant homology to known proteins, *ab initio* research is required to

identify their functions. For large dsDNA viruses, gene expression is usually categorized sequentially as immediate early, early, and late. Immediate early genes are expressed in the absence of *de novo* viral protein synthesis, early genes are involved in DNA synthesis, and late genes are expressed following viral DNA replication and encode the viral structural proteins and proteins required for assembly, maturation, and release of viral particles. Three immediate early genes, *ie1* (*wssv126*), *ie2* (*wssv418*), and *ie3* (*wssv242*), have been identified in WSSV-infected shrimp by showing that their transcription is not inhibited by cycloheximide. IE1 contains the Cys2/His2-type zinc finger motif, which is implicated in DNA-binding activity, suggesting that IE1 might function as a transcription factor. The gene products of *ie2* and *ie3* contain no recognizable functional motifs, and their functions remain unknown. Three latency–related genes have been identified: *wsv151*, *wsv427,* and *wsv 366.* These genes have been shown to be relatively highly expressed in asymptomatic carrier shrimp that tested negative for WSSV using a commercial PCR detection kit. When expressed as recombinant proteins in Sf9 insect cells, WSV151 is a nuclear protein of approximately 165 kDa, while WSV427 interacts *in vitro* with a novel shrimp serine/threonine protein phosphatase. A novel anti-apoptosis protein (ORF390) has also been identified. WSSV infection induces bystander, noninfected cells to undergo apoptosis, whereas WSSV-infected cells are not apoptotic. ORF390 has been shown to inhibit apoptosis induced either by infection with a mutant baculovirus or by treatment with actinomycin D. The protein has two putative caspase9 cleavage sites and a caspase3 cleavage site, and therefore might function like the AcMNPV P35 protein by directly binding to and inhibiting the activity of caspase9 and/or caspase3.

WSSV Gene Expression and Regulation

Since no suitable shrimp cell line is available, studies of WSSV gene expression have long been carried out *in vivo* in penaeid shrimp or crayfish by using RT-PCR. In the black tiger shrimp, *P. monodon*, WSSV immediate early and early genes (e.g., *rr1*, *rr2*, *pk1*, *tk-tmk*, *dnapol*, *ie1*, *ie2,* and *ie3*) are detected as early as 2–4 hpi (hours post infection) and their transcription levels either steadily and slowly increase till the end of the study (48 or 60 hpi) or else reach a plateau phase at 12–18 hpi. For late genes (the major viral structural protein genes), although very low levels could be detected as early as 2–4 hpi, transcription levels surged at 12–18 hpi and steadily increased thereafter. In crayfish, expression of the late genes was not observed until at least 18–24 hpi.

WSSV gene expression has been globally analyzed using microarrays. In one study, the results revealed that about 23.5% of WSSV genes began to express at 2 hpi, 4.2% at 6 hpi, 17.7% at 12 hpi, and 47.9% at 24 hpi. Most of the WSSV structural protein genes were expressed either at 12 hpi (9 WSSV structural protein genes) or at 24 hpi (14 WSSV structural protein genes). However, several structural protein genes were expressed at 2 hpi, suggesting that these proteins might also have important roles in the early infection stage. In another microarray study, clustering of the transcription profiles of the individual WSSV genes during infection showed two major classes of genes; the first class reached maximal expression at 20 hpi and the second class at 2 days post infection. Since most of the known WSSV early genes were found in the first class, the other genes in this class were also thought to be early genes. Conversely, the genes that clustered with the structural protein genes in the second class were likewise thought to be late genes. Therefore, RT-PCR and microarray studies suggest that, as for other large dsDNA viruses, the expression of WSSV genes is regulated in a coordinated series of cascades.

The promoter regions of WSSV early and late genes have been analyzed. The upstream region of WSSV early genes contains a TATA box and an initiator. This is similar to the *Drosophila* RNA polymerase II core promoter sequences, suggesting that the WSSV early genes are under the control of cellular transcription machinery. Alignment of the regions upstream of all the major structural protein genes has identified a degenerate motif (ATNAC) that could be involved in WSSV late gene transcription, while only one of these genes was found to contain a functional TATA box. These differences between the promoter regions of the early and late genes are sufficient to account for the differential transcription patterns between early and late genes, and they also suggest that WSSV uses at least two different classes of transcription machinery for gene expression. Since the WSSV genome contains no homologs of RNA polymerase subunits, at least one novel transcription factor (e.g., IE1, IE2, or IE3) would need to be induced at the early infection stage. These factors, which are presumably able to recognize a late gene-specific motif (such as the 'ATNAC' motif), could then recruit the host cellular transcription machinery to transcribe the late genes.

Viral–Host Relationships

Apoptosis

Apoptosis is a cell suicide program that enables multicellular organisms to direct and control cell numbers in tissues and to eliminate cells, including virus-infected cells that may be harmful to the survival of the organism. If apoptosis occurs during the early stage of infection, virus production is severely limited; because it inhibits the spread of progeny virus in the host, apoptosis is recognized as an antiviral defense. In consequence, most animal viruses

have evolved strategies to evade or delay an early apoptosis response. The classical signs of apoptosis can be identified in WSSV-infected shrimp, including nuclear disassembly, fragmentation of DNA into a ladder, and increased caspase3 activity. Furthermore, there is a positive correlation between the severity of WSSV infection and the number of apoptotic cells. Among the WSSV target tissues, the subcuticlar and abdominal epithelia are the most seriously damaged, and these epithelial tissues exhibit the highest incidence of apoptotic cells. However, it is significant that cells displaying apoptotic characteristics do not contain virions, whereas those containing WSSV virions are not apoptotic. It is therefore reasonable to suppose that apoptosis is employed by shrimp as a protective response to prevent the spread of WSSV, while in the infected cells, the anti-apoptosis protein ORF390 blocks apoptosis and thus facilitates multiplication of the virus.

Hemocyte Responses to WSSV Infection

In crustaceans, the hemocytes (blood cells) mediate many defense-related activities that are essential for the nonspecific immunity, including phagocytosis, melanization, encapsulation, cytotoxicity, and clotting. They also produce a vast array of antimicrobial proteins, such as agglutinins, antimicrobial peptides, and lysozymes. Hemocyte responses to WSSV have been investigated thoroughly in penaeid shrimp and crayfish. WSSV infection decreases the total hemocyte count (THC) in shrimp but not in crayfish. The reduced THC in shrimp is probably due to lysis by the virus of infected hemocytes as well as due to virus-induced apoptosis in both circulating hemocytes and hematopoietic tissue. In addition, circulating hemocytes migrate to tissues that have a high number of virus-infected cells, although this is probably a general defensive response rather than a specific antiviral response. WSSV infection also induces apoptosis in crayfish hemocytes but the percentage of apoptotic hemocytes is much lower in crayfish (1.5%) than in shrimp (20%).

WSSV infection differentially affects the three morphologically and functionally distinct hemocyte types that have been identified in crustacean hemolymph, commonly referred to as semigranular cells (SGCs), granular cells (GCs), and hyaline cells (HCs). In shrimp and crayfish, both SGCs and GCs can be infected with WSSV but SGCs are the preferential target. This suggests that SGCs are more susceptible to WSSV and that the virus replicates more rapidly in SGCs than in GCs. However, the melanization activity of GCs in WSSV-infected crayfish is reduced. The third type of hemocyte (HC) is refractory to WSSV infection in shrimp but their role in antiviral defense is still not clear. On the other hand, GCs and SGCs each play a major defensive role and WSSV infection of these cell types is likely to weaken shrimp defenses and reduce shrimp health. Since hemocytes are also necessary for clotting, the low THC also accounts for the phenomenon that hemolymph withdrawn from WSSV-infected shrimp and crayfish always has a delayed (or sometimes completely absent) clotting reaction.

Protection of Shrimp Against WSSV Infection Using Vaccination and RNAi Strategies

Since the earliest outbreaks of WSD, several advances have been made in our understanding of how shrimp might be protected against WSSV infection. For example, although it is generally thought that shrimps lack the immunoglobulin-based adaptive immune system, recent studies have shown that when *Penaeus japonicus* shrimps survive either natural or experimental WSSV infections, they sometimes show resistance to subsequent challenge with WSSV. This 'quasi-immune response' suggests that shrimps may have an innate immune system that includes specific memory. Further research into this phenomenon has shown that intramuscular injection or oral administration of either inactivated WSSV virions or recombinant structural protein VP28 similarly provide shrimps and crayfish with some degree of protection against WSSV infection. Another potential means of limiting WSSV infection is to take advantage of the *in vivo* roles of RNA interference induced by dsRNA. In *Litopenaeus vannamei* shrimp, whereas long dsRNA was shown to induce both sequence-dependent and sequence–independent antiviral responses, WSSV gene-specific dsRNAs produce strong anti-WSSV activity. Similar results have also been reported for the gene-specific dsRNAs of another shrimp virus, yellow head virus. However, the anti-WSSV activity of WSSV gene-specific dsRNAs varies greatly from one WSSV gene to another, and the effectiveness of each candidate needs to be tested empirically. Further, the antiviral activity of WSSV gene-specific small interfering RNA (21–23 bp dsRNA) has not yet been conclusively demonstrated.

Y

Yatapoxviruses

J W Barrett and G McFadden, The University of Western Ontario, London, ON, Canada

© 2008 Elsevier Ltd. All rights reserved.

Introduction

The most recently accepted ICTV designation for the *Poxviridae* includes a new primate genus in the subfamily *Chordopoxvirinae*. The genus *Yatapoxvirus* contains two recognized members: the type species, *Yaba monkey tumor virus* (YMTV) and *Tanapox virus* (TPV).

History

Poxvirus members of the genus *Yatapoxvirus* have been identified relatively recently following infection of monkeys at primate centers in Nigeria (1957) and in several states of the USA (1967), and infection of native African populations of equatorial Africa (late 1950s and early 1960s). YMTV infection produces benign histiocytomas in man and monkeys that rapidly proliferate, leading to large subcutaneous masses that are considered benign tumors. TPV infection causes localized, dermal lesions which are located on the extremities and which resolve slowly. The yatapoxviruses have been shown to infect humans and other primates only (**Table 1**). Based on genomic sequence data and morphology studies, the yatapoxviruses are structurally similar to other members of the *Poxviridae*.

YMTV was first observed following a spontaneous outbreak of subcutaneous tumors in a colony of captive rhesus monkeys housed in open-air pens in June 1957 at Yaba, near Lagos, Nigeria. The superficial growths were first observed in a single rhesus monkey and subsequently spread to 20 of 35 rhesus monkeys from that colony over the following several weeks. Although this primate center housed several other species in close proximity, only a single other species of primate (dog-faced baboon) was affected during this outbreak. The lesions in all cases eventually regressed.

TPV was first identified (1957) following two outbreaks among local people living in villages along the Tana River of Kenya. The illness was characterized by acute febrile reaction and associated pox-like skin lesions. A more widespread illness of 50 cases occurred in 1962 that included both genders and a spread of ages. The observation that the infection occurred during years of dramatic floods and increased mosquito activity, and the fact that the lesions appeared only on areas of exposed skin suggested that a biting insect, most likely a mosquito, was the vector of transmission. Virus isolated from infected humans could only be grown *in vitro* on various human and monkey cell lines. In addition, further transmission of infection by the inoculation virus was successful only in man and monkey. Therefore, most likely, an undefined local monkey species acts as the reservoir species for TPV.

Supporting these conclusions was the occurrence of mild poxvirus infections in three primate centers in the USA in 1966. The affected monkeys, mainly rhesus macaques, exhibited lesions that were similar in appearance and histology to those of the native Kenyans infected with tanapox. The lesions were hypertropic, slow in developing, with little evidence of vesiculation, and these characteristics were quite different from the lesions produced by a similarly appearing nodule that arises from monkeypox infection of man. In addition, at least two handlers at these centers contracted an infection which produced symptoms and lesions that clinically and histologically resembled tanapox infection.

Taxonomy and Classification

The prefix 'yata' is a contraction from the names of the two recognized members of the yatapoxviruses: *ya*ba monkey tumor virus and *ta*napox virus. The members of the yatapoxviruses are closely related by sequence similarity, serology, and immunodiffusion tests. This genus is comprised of only two recognized members (YMTV and TPV) that so far have only been shown to infect primates, including humans. The members of this genus are immunologically distinct from members of the seven other *Chordopoxvirinae* genera. Vaccination by poxviruses from other genera, including vaccinia virus, will not protect from infection by

Table 1 Members of the *Yatapoxvirus* genus

Member	*Abbreviation*	*Natural host*	*Major arthropod vector*	*Natural host disease*	*Length of infection*
Yaba monkey tumor virus	YMTV	Monkeys of Africa and Malaysia	Probably mosquito	Large, multicellular masses (2–5 cm)	Spontaneously regresses 6–12 weeks
Tanapox	TPV	Humans	Probably mosquito	Individual, round, raised nodules	Resolution in 3–4 weeks
Yaba-like disease	YLDV	Captive primates/ human handlers	Probably mosquito in monkeys, possibly scratches or bites to human handlers	Individual-few raised nodules	Resolution in 3–4 weeks

the yatapoxviruses and, conversely, a previous infection with a yatapoxvirus will not block other poxvirus infections.

A third member, yaba-like disease virus (YLDV), considered a strain of TPV, has been isolated from monkeys and their human handlers at several primate centers in the USA. Although ICTV does not recognize YLDV, the complete genomic sequence has been deposited in GenBank and provides scientists with genetic information about the closely related TPV.

Properties of the Virion

Morphologically, the yatapoxvirus viruses resemble typical oval-shaped poxvirus virions. YMTV and TPV particles contain a lipid outer membrane, inner membrane, and enclosed dumbbell-shaped core and lateral bodies. The virus measures between 250 and 300 nm on the long axis.

DNA Replication, Transcription, and Translation

Generally, viral DNA replication and protein synthesis of the yatapoxviruses is similar to, albeit slower than, the prototypical poxvirus, vaccinia virus. Yatapoxvirus DNA synthesis occurs in the cytoplasm of infected cells in 'virus factories'. Sequencing has confirmed that the genomes of the yatapoxviruses encode the standard suite of conserved poxvirus housekeeping genes, including transcription factors and enzymes required for viral replication, transcription, and translation.

One consistent difference between YMTV and other poxviruses has been the observation that YMTV replicates more efficiently *in vitro* at 35 °C rather than 37 °C. The reason for this temperature sensitivity is undefined; however, it may be the result of a required viral-encoded enzyme that is temperature sensitive or prolonged passage in a poikilothermic, nonmammalian host. Regardless, the cycle of replication follows standard poxvirus early gene expression, DNA synthesis, late gene expression, and morphogenesis. Viral DNA synthesis is detected as early as 3 h post infection (p.i.). Progeny virus first appears at 24 h p.i. *in vitro* and plateaus at 72 h p.i. This replication cycle is six to ten times longer than for vaccinia virus. YMTV has a narrow host range in tissue culture. In addition, *in vitro* infection involves a prolonged replication cycle and generally low virus yield. Continuous cells from cercopithecus monkey kidney cells (CV-1) are susceptible to YMTV infection; however, cell lines derived from other monkeys (BGMK, OMK) and other species (e.g., HeLa, RK13, and CEFs) do not support productive infection.

In contrast, TPV replication is most efficient at 37 °C. TPV replication follows the typical cascade of poxvirus DNA synthesis and production of infectious progeny but exhibits slower kinetics when compared to vaccinia virus, although it is much faster than YMTV. The eclipse period ranges from 24 to 48 h p.i.; however, this variation is dependent on the multiplicity of infection.

Transient expression of native yatapoxvirus genes from standard mammalian expression vectors results in low-to-no protein expression. However, if the viral coding sequence is optimized to favor the use of more commonly used human codons, the result is generally much higher protein expression levels from transfected human cells.

Properties of the Genome

The members of the yatapoxviruses encode the smallest characterized genomes within the *Poxviridae* (**Table 2**). Complete genomic sequencing information is now available for all yatapoxviruses. The genomes of the yatapoxvirus members are very A+T- rich, a characteristic shared by other members of the *Poxviridae* including members of the ortho-, sui-, capri-, and avipoxviruses. The YMTV genome is 70% A+T, 134.7 kbp long, and encodes for 140 genes. In contrast, TPV is 144.6 kbp, 73% A+T, and encodes for 155 genes (**Table 2**). Comparison between the complete YLDV sequence and the sequenced genomes of TPV indicates a high degree of sequence identity of approximately 98%, supporting the claim that TPV and YLDV are strains of the

Table 2 Features of the yatapoxvirus genomes

Member	*Genome size (bp)*	*Single copy genes*	*Duplicated genes*	*Terminal inverted repeat (bp)*	*% A + T*
TPV	144 565	155	1	1868	73
YMTV	134 721	139	1	1962	70.2
YLDV	144 575	150	1	1883	73

same virus. Comparison of the genomic sequences of YMTV and TPV indicates 78% identity. All of the genes identified in YMTV are also encoded by TPV; however, YMTV has lost 13 open reading frames (ORFs) found in TPV. The yatapoxviruses encode many of the same structural and housekeeping genes that are found in other poxviruses. The immunomodulatory genes of the yatapoxviruses also include a handful of novel genes predicted to be involved in regulation of immune response that are unique to the yatapoxvirus or are found in only a few other poxviruses. These include a new inhibitor of human tumor necrosis factor (TNF α (2L), virally encoded versions of chemokine receptors (7L and 145R), and TPV/YLDV (but not YMTV) encodes a viral IL-10 homolog (134R).

Immunity

YMTV and TPV show minimal to moderate cross-reactivity in collected sera. However, YMTV infection can protect nonhuman primates from TPV challenge. Monkeys infected with TPV and then challenged with YMTV exhibit reduced tumors and delayed symptoms. Comparison between YMTV and TPV infection identified both type-common and type-specific antigens. Circulating neutralizing antibodies, although present in the sera of several species of monkeys, are ineffective in preventing growth of YMTV tumors or reinfection. Immunity to superinfection is observed as long as tumors are present or regressing; however, following total tumor regression a new infection results in new tumor formation. Complement-fixing and complement-fixing-inhibiting antibodies are present in clinical and convalescent stages, respectively, of rhesus monkeys infected with either TPV or YMTV. The persistence of complement-fixing antibodies in monkeys infected with TPV is 10–12 weeks. Complement-fixing antibody was detected up to 35 weeks p.i. in monkeys infected with YMTV.

Tropism and Transmission – Humans

Naturally occurring YMTV infections have only been identified in nonhuman primates. However, accidental and volunteer infections have been established in humans. Infected humans develop lesions similar to those observed in monkeys although the proliferative responses are less pronounced and regression occurs earlier than in monkeys. Recovery of infectious virus from human lesions followed by serial passage and titration confirmed that YMTV was able to replicate productively in primary human tissue. Inoculation of rabbits, guinea pigs, hamsters, rats, mice, and dogs failed to produce proliferative lesions. In addition, no lesions were observed following inoculation of embryonated eggs. Testing of nonhuman primates suggests that rhesus and cynomolgus species are most susceptible as hosts.

TPV infections have only been identified in native populations of equatorial Africa or visitors to that region. The fact that infections appeared during years of extensive flooding, and that lesions are observed only on exposed areas of skin and occur on the extremities, suggests that transmission is via a biting arthropod vector (e.g., mosquitoes).

YLDV infection of monkey handlers at primate centers of the US exhibited a brief fever followed by production of a few raised, necrotic nodules that completely resolved.

Tropism – Nonhuman Primates

YMTV and YLDV have been identified from monkeys kept as research subjects at primate centers. Monkeys infected with YMTV were kept in open-air pens and infection spread from a single individual to other segregated monkeys, suggesting biting arthropods as the likely transmission vector. Research groups have screened sera collected from monkeys of various parts of the world for antibodies against either YMTV or TPV. Generally, antibodies against YMTV and TPV were identified from various monkey species from Africa, as well as cynomolgus monkeys from Malaysia, suggesting that these species suffer from infection, possibly subclinical, with TPV or YMTV. No antibodies to either virus were detected in Indian rhesus monkeys or from any of the monkey species tested from South America. Since rhesus monkeys are highly susceptible to clinical infection by both yatapoxviruses, it is surprising that none of the collected samples confirmed any previous infection. Although natural infection must be rare, the geographical location of the Indian primate species that are located between the African and Malaysian species (both of which were YMTV/TPV positive) suggests that negative serology results from primates in India may be misleading.

Pathogenesis

Infection of susceptible primates by YMTV targets histiocytes which rapidly divide and produce tumors. Histiocytes are cells, of either macrophage or Langerhans cell lineage, that migrate to areas of cellular disturbance. Following YMTV inoculation, histiocytes migrate to the site of virus inoculation during the first 48 h. The infiltrating histiocytes begin to exhibit cellular alterations, including enlargement of the nucleus and the prominence of nucleoli, by 72 h p.i. By day 5, the altered histiocytes become spindle shaped and exhibit mitotic activity. Also by day 5, inclusion bodies begin to become visible. Actively dividing cells begin to assume spiral forms between days 7 and 9 and acquire well-defined reticular patterns. By week 2, many degenerating cells along with other actively dividing cells become apparent. This scenario continues for the next 4–6 weeks. Eventually, the number of degenerating cells starts increasing and the number of dividing cells diminishes. Host immune response to infection is generally insignificant until regression of the lesion is nearly complete. At this point, there is evidence of lesion infiltration with host mononuclear cells. Necrosis of the center of the lesion is generally not part of the regression process; however, the tumor will exhibit surface ulceration. The beginning of degeneration is characterized by eosinophilic cytoplasmic mass, cytoplasmic lipid accumulation, vacuolization, and eventual cell dissolution. Tumor regression is not correlated to serum antibody titers. It is postulated that tumor regression is due to *in vivo* cytopathic effects rather than an innate immune response. However, the cytopathogenic effect of the virus eventually kills the cells and the tumor regresses. Natural regression can take up to several months, after which the individual is susceptible to reinfection.

TPV infection begins with a short febrile illness lasting several days that may include severe headaches, general fatigue, and body aches. This is followed by the appearance of a single, or a few, pock-like lesions that initially resemble those of variola. Tanapox lesions begin as a papule and develop into a hard, raised nodule and are normally located on the extremities. Nodules normally regress after 3–4 weeks.

Geographic and Seasonal Distribution

Naturally occurring yatapoxvirus infections have been extremely rare and geographically limited. TPV infections in human populations have only been observed in the equatorial belt of Africa between Zaire and Kenya. Recent TPV infections of humans have been limited to very few cases. Infection of human handlers with YLDV at primate centers in the US was effectively stopped by appropriate changes to biological safety conditions. YMTV infections have only been observed in nonhuman primates in Africa primate centers. Although a worldwide survey of primate sera has identified antibodies against YMTV in monkeys in both Africa and Malaysia, and TPV-neutralizing antibodies in native populations of equatorial Africa, the numbers of observed cases are rare.

The yatapoxviruses are probably transmitted by biting arthropod vectors (mosquitoes?) and therefore environmental conditions such as rainy seasons, excessive flooding, and natural occurrences that bring humans into closer contact with infected nonhuman primates will lead to increased observation of infections.

Immune Modulation

TPV is a self-limiting infection in humans and natural infection for YMTV has not been observed in humans. Only a small amount of research has been done on the molecular aspects of a TPV infection and none has been undertaken with YMTV. It is known that TPV-infected cells secrete a 38 kDa glycoprotein that has been shown to bind human interferon-γ, human IL-2, and human IL-5. In addition, the secreted, early protein 2L of TPV represents a new class of virally encoded tumor necrosis factor (TNF)-binding proteins found in the members of the yatapoxviruses, swinepox, and the unclassified deerpox virus. This 2L protein binds human TNFα with high affinity but is unable to bind other members of the human TNF superfamily. In addition, TPV 2L inhibits human TNFα from binding to TNF receptors I and II, as well as blocking TNF-induced cytolysis. However, 2L protein was shown to be unable to bind IFN-γ, IL-2, or IL-5 under experimental conditions.

TPV has been isolated from humans living in (or visiting) equatorial Africa and YLDV from workers at primate centers in the USA. The complete genomic sequence is presently available from TPV, YLDV and YMTV. Based on these sequences, it is clear that the TPV and YLDV genomes are 98% identical, which is clearly on the level of genetic similarity between strains of vaccinia virus. Based on the sequencing, a large number of host-modulating viral genes were predicted but only a handful have been studied. These include a new viral homolog of CCR8, a novel TNF inhibitor, and a viral-encoded member of the IL-10 family.

Epidemiology

YMTV is likely endemic in African monkeys. Neutralizing antibodies have been detected in monkeys from Africa and Malaysia, suggesting that YMTV possibly represents a latent infection in several monkey species. If this is true, it is surprising that monkeys from India have not yet been

reported to contain the same neutralizing antibodies. Infection in man has only occurred through injection of isolated YMTV.

The reservoir host for TPV is thought to be wild monkeys in equatorial Africa, from which natives can be infected by mosquito transmission. TPV infection is more common in years of heavy flooding when high water forces monkeys and man into closer proximity, while at the same time mosquito populations are at their zenith.

Prevention and Control

Control of YMTV and YLDV infection in man requires normal biological safety protocols to be exercised by animal handlers, including the wearing of protective clothing. TPV infection in equatorial Africa will require mosquito control measures. Separation of Asian and African monkey species at primate centers and markets and protective clothing for merchants and animal handlers may also help.

Future Perspectives

The reservoir status of primates with the yatapoxviruses is not a major human health concern. However, the features of infection, including YMTV targeting of histiocytes and tumor formation, the lack of long-term protection following regression of the initial infection, the observation that early TPV infection is difficult to distinguish from monkeypox infection, and the observation that members of this genus of poxviruses do in fact infect humans without eliciting an effective immune response may offer some unique insights into the mechanism of human zoonotic infections. Given the current concerns for early diagnoses of any and all human poxvirus infections, research on this group of poxviruses is likely to continue.

Decapping Removal of the methylated GMP in 5′–5′ linkage at the 5′ end of most eukaryotic mRNAs.

Ribosomal frameshifting Ribosomes changing reading frame on an mRNA, in response to a special mRNA structure, to synthesize a protein from two overlapping reading frames.

Introduction

The L-A virus of bakers/brewers yeast *Saccharomyces cerevisiae* is one of several RNA viruses infecting this organism, each of which spreads via the cell–cell fusion of mating, rather than by the extracellular route. The totivirus L-A, like members of the very similar L-BC family of viruses, is a single-segment 4.6 kbp double-stranded RNA (dsRNA) virus encapsidated in icosahedral particles with a single major coat protein called Gag.

The 20S and 23S RNA replicons are naked cytoplasmic single-stranded RNA (ssRNA) replicons except for their bound RNA-dependent RNA polymerases.

The L-A virus serves as the helper virus for any of several smaller satellite dsRNAs, called M dsRNAs, each encoding a secreted protein toxin and immunity to that toxin, producing the 'killer' phenomenon. Killer strains can eliminate some of the competition by this means, although only about 10% of wild strains harbor a killer dsRNA, suggesting there are costs to carrying this replicon. The killer phenotype was used to study the genetics of M dsRNAs and the helper L-A. Several functional variants of L-A were defined based on their interactions with different M dsRNAs and with the host, and host mutants affected in virus expression or propagation were also examined.

History

In 1963, Makower and Bevan reported that some yeast strains secrete a toxin that kills other yeasts This led to the identification by Bevan and by Fink of cellular dsRNAs and later viral particles correlated with the killer phenomenon. Studies of the chromosomal genes affecting the killer system revealed that the Kex2 protease, identified by its requirement for toxin secretion, was the long-sought proinsulin-processing enzyme. The Mak3 *N*-acetyltransferase, whose acetylation of Gag is needed for viral assembly, established consensus sequences for such enzymes. The loss of the L-A virus in *mak3* mutants revealed a second dsRNA species of the same size, called L-BC, and unrelated to the killer system.

Virion Structure

L-A virions have icosahedral symmetry, but contain 120 Gag monomers per particle, in apparent violation of the rules of quasi-equivalence. In fact, each virion is composed of 60 asymmetric dimers of Gag (**Figure 1**), a feature that is common to the cores of all dsRNA viruses that have been characterized. One type of Gag molecule makes contact with the icosahedral fivefold and twofold axes, but not with the threefold axes. The second type of Gag finds itself in contact with the threefold axis, but not with either the five- or twofold axes (**Figure 1**). The two environments of Gag lead to two distinct conformations, suggesting that Gag may be more flexible than some other coat proteins. The L-A virion has more volume per nucleotide than do ssRNA or dsDNA viruses. These facts may reflect the requirement that the dsRNA moves inside the particle and is transcribed by the RNA-dependent RNA polymerase that is fixed to the inner virion wall (see below). Pores at the fivefold axes are assumed to allow entry of nucleotides and exit of (+) strand transcripts, but retention of the dsRNA genome. A trench on the outside contains His154, the central active site residue of the mRNA-decapping activity to which the 7-methyl-GMP structure becomes covalently attached (**Figure 2**). A

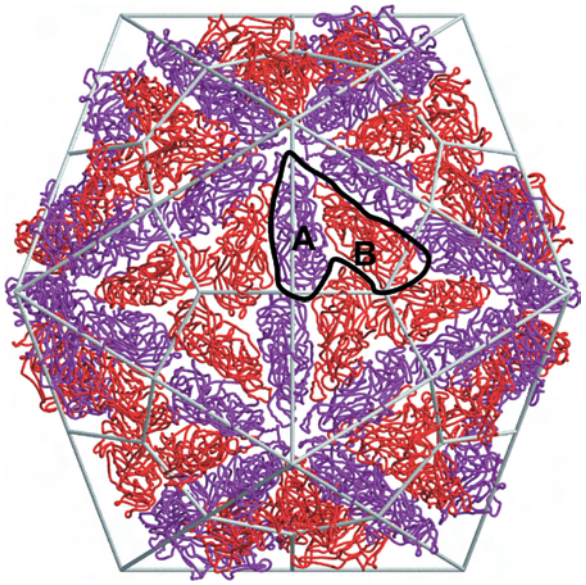

Figure 1 Wire diagram of the L-A virus capsid. The major coat protein, Gag, is found in two nonequivalent positions: 'A' molecules contact the fivefold and twofold axes, while 'B' molecules contact the threefold axes. Reproduced from Naitow I, Tang J, Canady M, Wickner RB, and Johnson JE (2002) L-A virus at 3.4 Å resolution reveals particle architecture and mRNA decapping mechanism. *Nature Structural Biology* 9: 725–728, with permission from Nature Publishing Group.

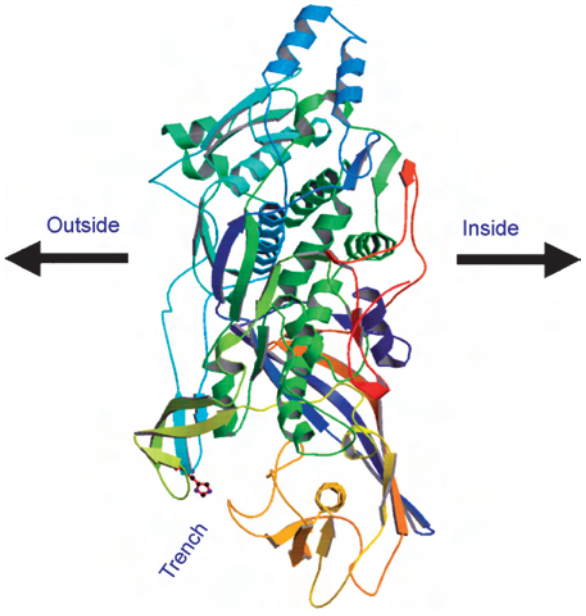

Figure 2 Ribbon diagram of a single Gag molecule. The trench on the outer surface includes His154, the Gag residue to which 7meGMP is covalently attached by the decapping activity.

layered density observed for the viral dsRNA may reflect the dsRNA's rigid structure and the fact that it is forced to press against the inner capsid wall.

Genome Organization

The single segment of the L-A genome is a 4.6 kbp dsRNA with two long open reading frames (ORFs) (**Figure 3**). The 5′ ORF encodes the major coat protein, called Gag in analogy with retroviruses, while the longer 3′ ORF, called Pol, encodes the RNA-dependent RNA polymerase, and has homology with similar enzymes of other ssRNA and dsRNA viruses. Pol is expressed only as a fusion protein whose amino end is a nearly complete Gag molecule. The fusion is carried out by a −1 ribosomal frameshift event in the region of overlap of the two ORFs. An RNA pseudoknot, in the region of overlap of the ORFs, slows ribosome progression at a point on the mRNA (of the form X XXY YYZ (0 frame indicated)) where bonding of the A-site and P-site tRNAs to the mRNA is nearly as good in the −1 frame as in the 0 frame. About 1% of ribosomes slip into the −1 frame, and, continuing translation, make the Gag–Pol fusion protein.

Replication Cycle

Transcription

Viral particles have an RNA-dependent RNA polymerase that is due to the Pol part of the Gag–Pol fusion protein. Transcription is a conservative reaction, meaning that the parental strands remain together after the synthesis of a new (+) strand. The L-A (+) strand transcripts are extruded from the particles into the cytoplasm where they serve as both mRNA and as the species that is packaged by coat proteins to make new viral particles. However, (+) strand transcripts of the smaller M dsRNA or of deletion mutants of L-A are often retained within the particle where they may be replicated. This is called 'headful replication' because the volume of the particle seems to be the determinant of how many dsRNA molecules may accumulate in each particle.

RNA Packaging

The RNA packaging site (**Figure 3**) is a stem–loop structure about 400 nucleotides from the 3′ end of the L-A (+) strand. This stem–loop has an essential A residue protruding on the 5′ side of the stem. The loop sequence is also important, but the stem sequence is not critical, as long as the stem structure can form. The packaging site on the RNA is recognized by the proximal part of the Pol domain of the Gag–Pol fusion protein. The Gag part of Gag–Pol is part of the capsid structure, so the Gag–Pol fusion protein structure assures packaging of viral (+) strands in new particles.

RNA Replication

The (−) strand synthesis reaction is called replication (**Figure 4**). This reaction involves recognition of the

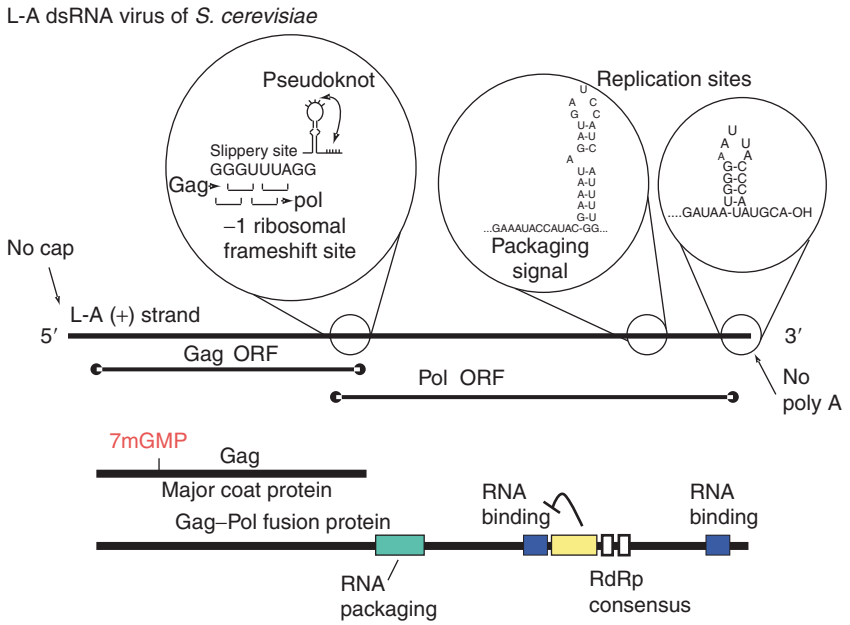

Figure 3 Genome organization. The L-A (+) strand encodes Gag and Pol in overlapping reading frames. The mRNA lacks 5′ cap and 3′ polyA structures. The location of the packaging site on the RNA and the region of the Pol protein segment (green box) that recognizes the packaging site are indicated. The RNA sites for replication, and the parts of Pol with homology to other RNA-dependent RNA polymerases (RdRp) are indicated. The cryptic *in vitro* RNA binding site (blue box) is inhibited by the area shown by the yellow box.

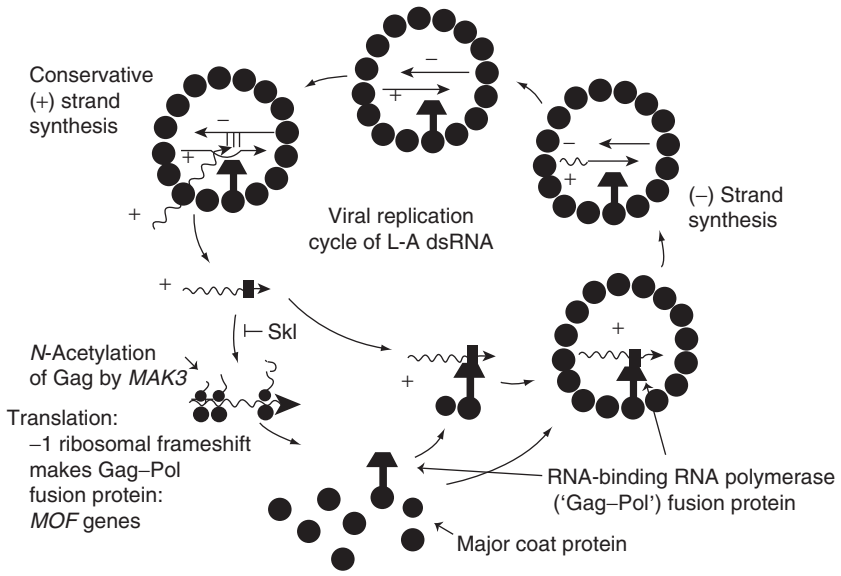

Figure 4 Replication cycle of the L-A virus. Both (+) and (–) RNA strand synthesis occur within the viral particles, but at different stages of the cycle. RNA (+) strands (transcripts) are extruded from the particles and serve as both mRNA and the species packaged to make new particles. Translation of viral mRNA is blocked by Ski proteins. N-terminal acetylation of Gag by Mak3p is necessary for viral assembly.

internal binding site on the L-A (+) strands by Pol, followed by interaction with the now nearby 3′ end and initiation of new RNA (–) chains. Multiple rounds of RNA synthesis can proceed within the viral particle in the 'headful replication' process discussed above.

Viral Translation

The translation apparatus is the battleground of RNA viruses with their hosts. Poliovirus protease cleaves eIF4G so that host-capped mRNAs cannot be translated but its own IRES-containing mRNAs are used. Influenza virus steals caps from host mRNAs.

L-A (+) strand transcripts lack both the 5′ cap and 3′ polyA structures typical of eukaryotic mRNAs, and so are at a distinct disadvantage. Mutations resulting in a relative deficiency of 60S ribosomal subunits selectively lose the ability to express cap-minus, polyA-minus mRNAs such as those of L-A. The *SKI* genes encode a series of proteins whose function is to specifically block the expression of non-polyA mRNAs. The Ski proteins have effects on both translatability of non-polyA mRNAs and on their stability. The *SKI1/XRN1* gene encodes a 5′→3′ exoribonuclease specific for uncapped mRNA. As a defense against its degradation of viral mRNA, L-A's Gag protein has a decapping activity that produces, from cellular mRNAs, 'decapitated decoys', uncapped RNAs that serve as alternative targets for the exonuclease action. In the absence of this decapping activity, viral mRNAs are not expressed, but deletion of the *SKI1/XRN1* gene restores viral mRNA expression.

L-A Genetics

Several natural variants of L-A have been described. The ability of an L-A variant to support M dsRNA replication was first called [HOK] (=helper of killer) and then H when it was found to be a property of L-As such as L-A-H, L-A-HN, or L-A-HNB. Making several chromosomal *MAK* genes dispensable for M propagation was named [B] (=bypass) and is found on L-A-HNB. Ability to exclude L-A-H was named [EXL] (=exclusion) and then just E on L-A-E. Insensitivity to the action of [EXL] was called [NEX] (=nonexcludable), and then shortened to N as in L-A-HN or L-A-HNB. The molecular basis of these interactions has resisted study because of the current inability to obtain L-A from a cDNA clone. M dsRNA can be supported from a cDNA clone of L-A, but the L-A virus has not been shown to be regenerated from these transcripts.

Other RNA Replicons in Yeast: L-BC, 20S RNA, 23S RNA

20S RNA was discovered as an RNA species which appeared when cells were placed under conditions that induce meiosis and spore formation, namely near-starvation for nitrogen and provision of acetate as a carbon source. It was shown that 20S RNA is an independent replicon, and can be made independent of the sporulation or meiosis processes. 20S RNA encodes its own RNA-dependent RNA polymerase which is bound to the otherwise naked cytoplasmic RNA. The mechanism of

20S RNA replication control by culture conditions remains to be elucidated.

23S RNA is a related, but independent yeast replicon which was found as a dsRNA form (called T). 23S RNA also encodes its RNA-dependent RNA polymerase. Both 20S RNA and 23S RNA can be launched from cDNA clones to form replicating virus.

L-BC is a totivirus, related to L-A but independent of it. Its dsRNA is essentially the same size as that of L-A although its copy number is usually about tenfold lower. Thus it was not detected until chromosomal mutants that lose L-A were examined. L-BC does not interact with the killer system, and confers no obvious phenotype, so its genetics has not been extensively explored.

Yellow Fever Virus

A A Marfin, Centers for Disease Control and Prevention, Atlanta, GA, USA
T P Monath, Kleiner Perkins Caufield and Byers, Menlo Park, CA, USA

© 2008 Elsevier Ltd. All rights reserved.

Glossary

Aedes A genus of mosquitoes strongly involved in the transmission of yellow fever virus. *Aedes (Ae.) aegypti* is a species belonging to the genus that breeds in close association with humans and is often responsible for epidemics of yellow fever.

Flavivirus A virus in the genus *Flavivirus*.

Genotype Genetic composition of an individual (virus), used to delineate relatedness of individuals.

Host A vertebrate species (including humans) infected by virus. An effective host is one that developes viremia sufficient to infect vectors and thus contributes to the virus transmission cycle.

Pathogenesis The process whereby virus infection proceeds in the host, leading to spread of the infection to vital organs and the development of damage to cells and tissues.

Transmission cycle The sequential infection of blood-feeding vectors and vertebrate hosts

responsible for maintaining and amplifying virus in nature.
Vector An arthropod (e.g., mosquito or tick) capable of becoming actively infected by blood feeding and of subsequently transmitting virus to a vertebrate host.

Introduction

Yellow fever virus (YFV) is the prototype species of the virus family *Flaviviridae* (and of the genus *Flavivirus*), which includes approximately 70 single-stranded RNA viruses, most of which are transmitted by mosquitoes or ticks. Other viruses in this family include the four dengue viruses, West Nile virus, Japanese encephalitis virus, and tick-borne encephalitis viruses.

History

Yellow fever (YF) is the original 'viral hemorrhagic fever', a systemic illness characterized by high viremia; hepatic, renal, and myocardial injury; hemorrhage; and high lethality. Genetic sequence analysis reveals that YFV diverged from the ancestral flaviviral lineage, roughly 3000 years ago, earlier than did other mosquito-borne flaviviruses. The first description of epidemic hematemesis occurred in Mexico in 1648, which suggests that the virus and its mosquito vector, *Aedes aegypti*, were introduced from Africa with the slave trade. Furthermore, monkeys of New World species are more susceptible to lethal infection than are African monkeys, also suggesting that YFV was recently introduced. The West African and South American genotypes of YFV are more closely related to each other than to other genotypes, indicating the probable source of introduction. During the eighteenth and nineteenth centuries, YF epidemics affected coastal cities in the Americas and Europe; the disease was likely introduced via ships infested with YFV-infected mosquitoes. In the mid- and late nineteenth century, physicians, most notably Carlos Findlay, suggested that YFV was transmitted by mosquitoes. In 1900, Walter Reed and colleagues demonstrated that the agent was a filterable virus transmitted by *Ae. aegypti* mosquitoes. In 1927, YFV was isolated from a Ghanaian man; efforts to establish continuous direct passage in animals resulted in establishment of the Asibi strain. Isolation of the Asibi strain and a contemporary ('French') strain isolated in Dakar, Senegal, enabled development of quantitative methods that allowed more precise scientific studies, as well as two live, attenuated vaccines.

Taxonomy, Classification, and Variation

YFV is antigenically distinguished from all other flaviviruses by neutralization test, and all strains of YFV belong to a single serotype. Among flaviviruses, YFV is more closely related to Wesselsbron, Sepik, Edge Hill, Bouboui, Uganda S, Banzi, Jugra, Saboya, and Potiskum viruses.

Wild-type YFV is genetically stable compared to other RNA viruses, likely due to restrictions imposed by replication in vertebrate and invertebrate hosts and maintained by a high-fidelity RNA-dependent RNA polymerase. Despite this stability, genomic sequence analyses of structural and nonstructural genes and of YFV-specific repeat sequences have identified at least seven distinct genotypes. Analyses indicate YFV arose in Africa and divided into West and East African genotypes prior to introduction into the Americas. Currently, five African genotypes are recognized – West Africa I, West Africa II, East/Central Africa, East Africa, and Angola. South American YFV can be divided into two genotypes – South America I (in Brazil) and South America II (in the western part of the continent). These genotypes demonstrate a high degree of homology but can frequently be clustered by time periods, geography, and by predominant transmission patterns.

Properties of the Virion

YFV virions are small (40–60 nm diameter), spherical, and have short surface projections. The icosohedral nucleocapsid contains the single-stranded RNA genome and a single core protein (C protein), and is surrounded by a lipid bilayer. Viral infectivity is rapidly inactivated by heat (56 °C for 30 min), ultraviolet radiation, and lipid detergents.

Properties of the Genome

The YFV genome is comprised of a single strand of plus-sense (i.e., infectious) RNA that contains 10 862 nt and is composed of a 118-nt 5′ noncoding region (NCR) preceded by a type 1 cap structure, a single open reading frame (ORF) of 10 233 nt that encodes 11 viral proteins, and a 511-nt 3′ NCR without a polyadenylated tail. The 5′ and 3′ NCRs have conformational structure and complementary sequences that are important in cyclization of the viral genome during encapsidation and replication and which function as promoters during replication. Mutations or deletions in these regions affect replication and virulence. The 3′ NCR contains conserved consensus sequences which pair with 5′ NCR sequences during cyclization and serve as the common recognition site for the viral polymerase. Directly upstream from these

sequences, the 3′ NCR forms a 3′ terminal hairpin structure and pseudoknots to serve as promoters for genomic replication.

Viral Proteins

The ORF encodes three structural proteins at the 5′ end (capsid (C), pre-membrane (preM), and envelope (E) proteins), followed downstream by 7 nonstructural (NS) proteins (NS1–NS2A–NS2B–NS3–NS4A–NS4B–NS5). The mature virion includes these three structural proteins, while the NS proteins are responsible for replication and polyprotein processing including cleavage of the polyprotein into proteins.

The C protein (MW ~ 11 kDa) interacts with genomic RNA to form the virion nucleocapsid, anchors the nucleocapsid to the endoplamic reticulum, and provides signal sequence to the preM protein. The preM glycoprotein (~27 kDa) forms an intracellular heterodimer to stabilize the E protein during exocytosis. During exocytosis, the preM protein is processed by a furin-like protease leaving a small M structural protein (~8 kDa) anchored in the virus envelope of the extracellular virion. The M protein spans the viral membrane and has exposed antigenic domains that may induce a minor immunologic response. Abnormal preM/M cleavage may result in incorporation of preM into mature virions that later affect E protein conformation, inhibit fusion, and reduce infectivity.

The E protein (~50 kDa) is the major surface structure glycoprotein. The three-dimensional configuration of the E protein forms three domains, is determined by disulfide bonding, and is critical for its role in cell tropism, membrane fusion, virulence, and immunity. Strain-, type-, and flavivirus group-specific epitopes are present in this glycoprotein. The hydrophobic C-terminus of this protein is anchored to the lipid bilayer of the viral envelope by a 170-Å-long rod. The C-terminus is connected by a flexible region to domain I, the central part of the molecule with up-and-down topology having eight antiparallel β-strands and containing the N-terminus. Inhibition of this flexible region results in decreased infectivity. Two long loops in domain II extend laterally and are responsible for dimerization. A conserved stretch of 14 amino acids in these loops is the fusion domain that allows internalization of the nucleocapsid into the infected cell. Domain III contains sites involved in binding cell receptors. Conformational neutralization determinants are scattered on the outer surface of all three domains.

The NS1 glycoprotein is involved in RNA replication through its interaction with NS4A and is both expressed on the cell surface and released extracellularly. The extracellular form contains virus-specific and cross-reactive epitopes. Antibodies to NS1 do not neutralize virus infectivity but do provide protective immunity by complement-mediated lysis and rapid clearance of cells with NS1 on the surface. NS1 is highly conserved across all YF strains. NS2A is a small protein (~22 kDa) that interacts with NS3, NS5, and 3′ NCR sequences and plays an important role in RNA replication and in the assembly or release of virions. NS3 (~70 kDa) and NS2B (~14 kDa) interact to form a complex with important enzymatic functions, including serine protease (responsible for post-translational cleavage of virus polyprotein), RNA helicase, and RNA triphosphatase activities. Because of its critical functions, the NS3 gene sequence is also highly conserved. NS3 is also present in cell membranes, contains virus-specific T-cell epitopes that are targets for cytotoxic T-cells. The NS4A (~16 kDa) and NS4B (~27 kDa) proteins are membrane associated and play a role in regulating RNA replication. The NS5 protein (~103 kDa) is a highly conserved RNA-dependent RNA polymerase in virus replication and methyltransferase during 5′ cap methylation.

Assembly and Replication

Assembly of these proteins into viral particles and subsequent exocytosis of mature virions occur in close association with the endoplasmic reticulum of secretory cells (e.g., mosquito salivary gland and various mammal exocrine and endocrine glands). Virion assembly occurs in concert with host cell secretory components and virions are released in secretory granules without significantly disturbing host cellular function or macromolecular synthesis.

After release, virions enter uninfected host cells by attaching to still-undefined receptors and are taken up in clathrin-coated vesicles. Following an acid-mediated change in the E protein that allows fusion of the virus with the host's endosomal membrane, nucleocapsids are released from the vesicles into the cytoplasm. The full-genome-length, plus-sense RNA is translated to make complementary minus strands that serve as templates for progeny plus strands. These plus strands serve as mRNAs for translation of structural and NS proteins including enzymes required for continued virus production and post-translational cleavage of the polyprotein; as templates for the transcription of new minus-sense strands; and as genomes of newly produced mature virions.

Molecular Determinants of Virulence

The entire genomes of the 17D and Asibi strains and of the French neurotropic vaccine and French viscerotropic strains have been sequenced and compared. Comparing sequences and different biological properties of these

pairs allows insight into molecular determinants of virulence. Although some potentially important specific sequences have been identified, virulence is clearly multigenic and determined by nonstructural and structural genes. Most studies on these molecular determinants have employed mouse models. Because mice manifest neurotropism and not viscerotropism, such studies are of limited value in dissecting pathogenesis. More recent studies in hamsters susceptible to lethal hepatic dysfunction and necrosis resembling wild-type YFV may allow identifying genetic sequences associated with viscerotropism, but YFV strains must be adapted by serial passage in hamsters before they elicit disease. Nonhuman primates are susceptible to wild-type YFV strains and develop a syndrome closely resembling that in humans.

The 17D and Asibi strains differ at four nucleotides in the 3′ NCR and 20 amino acids in the coding region – eight in the E gene; four in the NS2A gene; two in the NS5 gene; and one each in the M, NS1, NS2B, NS3, NS4A, and NS4B genes.

Given the functional importance of E protein in attachment of YFV to and entry into the cell, one or more of the amino acid differences in this protein likely plays a role in attenuation. Mutations in three areas of E protein alter virulence properties – the tip of the fusion domain in domain II, the molecular hinge between domains I and II, and the portion of domain III containing the putative receptor ligand. Of the eight amino acids that distinguish E proteins of Asibi and 17D viruses four are nonconservative, suggesting that one or more may be responsible for attenuation. Three of these nonconservative changes occur in the hinge region and likely alter the acid-dependent change in E protein conformation required for virus entry. Of nonconservative mutations outside of the hinge region, two (E305 and E380) are located in domain III, which contains determinants involved in tropism and cell attachment. The mutation at amino acid E380 of YF 17D occurs in the putative integrin cell receptor. Studies of this region in other flaviviruses also suggest that mutations in the putative cell receptor-binding region of domain III play a role in determining neurovirulence.

Other studies emphasize the multigenic nature of virulence and suggest that one or more of the 11 amino acid changes in NS proteins, or base changes in the 3′ NCR, may contribute to attenuation. Studies with other flaviviruses have shown that mutations in the NS proteins reduce neurovirulence, probably because NS proteins are critical to the virus replication mechanism. Eleven amino acid changes in the NS proteins of Asibi strain viruses occurred during derivation of the 17D vaccine strain. These changes in NS proteins may affect assembly or release of YFV particles, changes in the RNA helicase and triphosphatase enzymes for unwinding RNA during replication, and activity of the RNA-dependent RNA polymerase. Similarly, the 3′ NCR terminal region is involved in folding of the stem–loop structure which serves as a critical promoter during replication. Changes in this sequence or the number of repeat sequences may alter the stem–loop region, interfere with virus replication, and contribute to attenuation.

Little is known about the determinants of YFV viscerotropism (the ability of YFV to replicate and damage non-neural tissue, such as the liver) principally because assessing this property in nonhuman primates is difficult. Because neuro- and viscerotropic properties may reside in distinct regions, one cannot conclude that attenuation of one correlates with attenuation of the other. However, the hinge region of the E protein contains residues implicated in both neurotropism and viscerotropism. Studies in golden hamsters, which develop disease resembling human YFV, suggest that domain III sites implicated as cell receptor ligands are responsible for hepatotropism.

Host Range and Virus Propagation

A highly conserved region in the domain III of the E protein contains an arginine-glycine-aspartic acid (RGD) motif and is the likely site of virus-cell attachment. Because of the broad host range of flaviviruses, the receptors are highly conserved structures found in chordate and arthropod phyla. YFV replicates and produces cytopathic changes and plaque formation in a wide variety of cell types including primary chick and duck embryo cells; continuous porcine, hamster, rabbit, and monkey kidney cell lines; and cells of human origin such as HeLa, KB, Chang liver, and SW-13. The virus replicates in Fc receptor-bearing macrophages and macrophage cell lines; replication is enhanced by antibody. Mosquito cell lines, especially AP-16 cells, are highly susceptible and often used for primary isolation or efficient laboratory propagation.

Virus isolation is accomplished by intrathoracic inoculation of *Toxorhynchites* or *Ae. aegypti* mosquitoes, inoculation of mosquito cell line cultures (i.e., AP61 and C6/36 cells), intracerebral inoculation of suckling mice or inoculation of specific nonhuman primates. Intrathoracic inoculation of mosquitoes is the most sensitive method. Because infected mosquitoes show no signs of infection, virus is demonstrated by immunofluorescence, subsequent passage to a susceptible host, or amplification of YFV RNA sequences by reverse transcriptase-polymerase chain reaction (RT-PCR). AP61 cells are more sensitive than other *in vitro* methods for primary isolation and show cytopathic effects within 5–7 days of inoculation. Immunofluorescence assays to identify viral antigens and RT-PCR to identify RNA sequences are positive before development of cytopathic effects.

Susceptible vertebrate hosts that show signs of infection include infant mice, which develop fatal encephalitis when

infected by peripheral or intracerebral routes; mice greater than 8 days old develop fatal encephalitis only following intracerebral challenge. Nonhuman primates of many species develop fatal hepatitis resembling human disease. The only nonprimate species that develop lethal hepatitis following infection are the European hedgehog and the golden hamster. Antibodies to YFV have been found in a wide variety of field-collected wild vertebrates and wild animals such as rodents and bats. With the exception of opossums in South America, there is no support for a role of nonprimate species in the transmission cycle.

Geographic and Seasonal Distribution

YF occurs in tropical South America and sub-Saharan Africa, where the enzootic transmission cycle involves tree-hole-breeding mosquitoes and nonhuman primates. *Aedes aegypti*-infested regions of Central and North America, the Caribbean, and Southern Europe had periodic outbreaks through the early 1900s and are considered at risk, should the virus be reintroduced. Despite the prevalence of *Ae. aegypti* in tropical Asia, YFV has not appeared. Cross-protection by immunity to dengue viruses may decrease the probability that YFV can be transported from inaccessible, endemic parts of Africa and South America. Low vector competence of Asian populations of *Ae. aegypti* may be responsible for diminishing the risk of virus transmission. Areas at highest risk for reintroduction of virus and secondary spread by re-emerging *Ae. aegypti* include coastal regions and interior towns throughout equatorial South America, Panama, Central America, the West Indies, Mexico, and the southern United States. All are areas affected by YF in the past.

Breeding of many mosquito species that transmit YFV occurs in tree holes and is dependent on rainfall; consequently, transmission increases during tropical rainy seasons and decreases or stops during dry seasons. The peridomestic vector *Ae. aegypti* breeds in receptacles used by humans for water storage, and is less dependent on rainfall. Where this mosquito is involved in virus transmission, YF may occur in the dry season in both rural and urban areas. Temperature also influences YFV transmission rates; a few degrees increase may shorten the extrinsic incubation period (a period of viral replication in a recently infected mosquito prior to the mosquito being capable of transmitting virus to a host) by days, resulting in a significantly increased rate of transmission. Warm temperature also increases biting and reproductive rates of *Ae. aegypti.*

Disease Incidence

Official notifications of disease likely underestimate disease incidence and case–fatality rate, although underreporting occurs to variable degree. During the 20-year period ending in 2004, 28 264 cases and 7880 deaths were reported to the World Health Organization (WHO). In Africa, which accounted for 24 684 cases (87%), the annual incidence varied between 1 and 5104 cases, suggesting highly variable reporting. Despite inconsistent reporting, enzootic and endemic transmission was known to occur continuously in affected regions. During this period, Africa reported 5815 or 74% of the worldwide deaths due to YF, with a case–fatality rate of 24%. The frequency and intensity of epidemics in Africa are due to interhuman transmission by mosquito vectors present in high-density, high-human populations, and low immunization coverage. West Africa appears to be at highest risk of YF emergences, probably reflecting the role of domestic *Ae. aegypti* mosquito vectors. In South America, YF occurs in the Amazon region and contiguous areas. Between 1985 and 2004, 3580 cases and 2074 deaths (case–fatality rate 58%) were reported to WHO by South American countries. The annual incidence varies by country due to fluctuating epizootic activity. The incidence of YF in South America is roughly 20% of that of Africa, due to transmission by enzootic as opposed to epidemic vectors, lower densities of vectors, monkeys and human hosts, and relatively high vaccination coverage. The higher case–fatality rate in South America probably reflects the reporting of more severe cases there, and the fact that surveillance there is based on death reports and postmortem liver examination, although it remains possible that the South American genotype(s) is more virulent than those in Africa.

Epidemiology and Transmission Cycles

YFV is present at high titers in the blood of infected, susceptible hosts (humans and nonhuman primates) for several days, during which mosquito vectors collecting a blood meal may become infected. Virus replicates sequentially in the midgut epithelium, body, and salivary glands of the mosquito. The period between the infecting blood meal and the point at which sufficient replication allows transmission to a vertebrate host is the 'extrinsic incubation period'. This is a temperature-dependent process and takes roughly a week to complete.

Transmission cycles differ according to the hosts and vectors involved. Although the resulting clinical disease does not differ, recognizing the type of cycle is important for disease control. The 'urban cycle' involves humans as the viremic host and *Ae. aegypti* breeding in peridomestic, man-made containers that hold unpolluted water. The 'sylvatic cycle', the predominant pattern in equatorial rain forests of Africa and South America, involves transmission between nonhuman primates and tree-hole-breeding mosquito vectors. In Africa, a third cycle, the

'savanna cycle', is recognized in moist grasslands bordering the rain forests where *Aedes* mosquitoes other than *Ae. aegypti* feed on both humans and nonhuman primates. In all of these settings, the rate of transmission varies widely depending on the density of vectors and the presence of susceptible primates. Primates of many nonhuman species are susceptible to YFV infection. Most African primates produce viremias sufficient to infect mosquitoes without developing illness, whereas many South American primates develop lethal infections. Depletion of vertebrate hosts through natural immunization and death during epizootic waves is a factor in the cyclic appearance of YF activity. In many areas, with environmental pressures markedly reducing monkey populations, human beings serve as hosts in the YFV transmission cycle. No nonprimate species are involved in enzootic transmission.

The risk of nonimmune persons becoming infected is determined by geographic location, season, activities that lead to exposure, duration of exposure to mosquito bites, and the intensity of YFV transmission. Although reported cases of human disease are an important guide to YFV activity, reported numbers may be low due to a high level of immunity in the population or to insensitive surveillance. In areas where vaccination is widely practiced, YFV may circulate between monkeys and mosquitoes, with few human cases occurring.

The means of survival of YFV across long dry seasons, when sylvatic mosquito vectors are absent, remains in question. Transovarial transmission to *Aedes* and *Haemagogus* mosquito eggs, which survive desiccation in tree holes and hatch when the rains return, likely play a major role. Low-level horizontal transmission by drought-resistant vectors, and alternative horizontal and vertical transmission cycles involving ticks, are theorized mechanisms. Although persistent infection of experimentally infected nonhuman primates has been documented, infections in these hosts generally are not accompanied by viremia sufficiently high to infect vectors.

The most alarming future prospect involves the reemergence of urban transmission in South America and the spread to heavily populated, *Ae. aegypti*-infested areas currently free from disease, such as the coastal regions of South America, the Caribbean, and North America, and regions where the virus has never become established but which have susceptible human populations and competent mosquito vectors, such as the Middle East, coastal East Africa, the Indian subcontinent, Asia, and Australia. Alterations in human demography and behavior, in virus activity, and in the distribution of *Ae. aegypti* underlie the potential for epidemiological change. Such alterations include: (1) increasing urban populations; (2) changes in commerce, transportation, and communication that allow human population expansion into previously remote endemic zones; (3) reinvasion of South America by the peridomestic *Ae. aegypti*; (4) presence of efficient jungle vectors in degraded periurban habitats; (5) introduction of new competent *Aedes* species (e.g., *Ae. albopictus*) that may bridge the jungle and urban transmission cycles; (6) relaxation of regulations and of enforcement of vaccination certification for travelers; and (7) possibly climate change.

Laboratory-acquired infections were common in the pre-vaccine era and remain of concern today, particularly where unvaccinated clinical laboratory personnel encounter blood from patients in early stages of illness. Some laboratory infections were probably acquired via bites of experimentally infected mosquitoes or of wild mosquitoes infected after feeding on experimental animals. Others resulted from direct contact with blood or aerosols of dried virus. The stability of YFV permits transmission within a short period after generation of an infectious aerosol.

Clinical Features

The broad clinical spectrum of YF includes abortive infection with nonspecific flu-like illness, and 'classic' YF – potentially lethal pansystemic disease with fever, jaundice, renal failure, and hemorrhage. Serosurveys to identify persons with asymptomatic infections estimate that only about 15–25% of infected persons develop classic YF. Diagnosis of sporadic cases without classic symptoms is difficult; as a result, often only cases of classic YF are notified, and deaths may be more frequently notified than cases. These features lead to an underestimate of morbidity and overestimate of case–fatality rate. The variability in clinical response to infection is multifactoral and includes intrinsic and acquired host resistance factors and differences in pathogenicity of virus strains.

Classic YF is a triphasic disease that begins with abrupt onset of fever, headache, myalgia, anorexia, and nausea 3–6 days after infection. This 'period of infection' is clinically nonspecific but corresponds to a viremic phase when a person is infectious to feeding mosquitoes. Fatal cases appear to have a longer duration of viremia than do survivors. After 3–4 days, a 'period of remission', lasting up to 48 h, begins with abatement of fever and symptoms. Cases of abortive infection simply recover at this stage. Because such cases remain anicteric with nonspecific symptoms, clinical diagnosis of YF is not possible. Roughly 15–25% of persons infected with YFV enter a 'period of intoxication', typically 3–5 days after onset, characterized by a moderate to severe disease characterized by jaundice, the return of fever, relative bradycardia, oliguria, hemetemesis, and other hemorrhagic diatheses. Virus disappears from blood and antibodies appear 7–10 days after infection. The subsequent course reflects dysfunction of the hepatic, renal, and cardiovascular systems. Central nervous system (CNS) signs include delirium, convulsions, and coma. In severe cases, the cerebrospinal fluid is under increased pressure and may

contain elevated protein but no cells. No inflammatory changes have been found in brains of persons with severe illness; cerebral edema or metabolic factors apparently cause CNS signs. Between the fifth and tenth day of illness, the patient either dies or recovers rapidly. Terminal events are characterized by hypotension, shock, and respiratory distress.

Pathology and Pathogenesis

Two biological properties are inherent to all wild-type YFV strains: 'viscerotropism', the ability to cause viremia and subsequently to infect and damage liver, heart, and kidneys, and 'neurotropism', the ability to infect the brain parenchyma causing encephalitis. Wild-type YFV strains are predominantly viscerotropic in humans and in nonhuman primates. True YF viral encephalitis is rare; even after intracerebral inoculation of YFV, susceptible nonhuman primates die from hepatitis rather than from encephalitis.

The course of infection following inoculation of wild-type YFV has been partially investigated using nonhuman primates. Virus replicates at the site of skin inoculation and spreads to draining lymph nodes, then to central lymph nodes, and subsequently to visceral organs. Lymphoid cells are early viral replication sites, and in the liver Kupffer cells in the sinusoids are the gateway to subsequent hepatocyte infection. Results of prior research, primarily of dengue infections, makes clear that dendritic cells (DCs) play a primary role in the early stages of infection, and that these cells not only process viral antigens into immunogenic peptides and present them to T-cells, but also secrete a cascade of immunoregulatory cytokines that shape innate and adaptive immune responses.

In humans with viscerotropic disease, degeneration of hepatocytes occurs in the last phase of infection. In fatal cases, up to 100% of hepatocytes undergo coagulative necrosis characteristic of apoptosis. The mid-zone of the liver lobule is principally affected, with sparing of cells bordering the central vein and portal tracts. Viral antigen and viral RNA are demonstrable in cells undergoing pathological changes, suggesting that cytopathology is mediated by direct injury from virus replication and from accumulation of virions and viral protein in the endoplasmic reticulum. The reason for this peculiar distribution of hepatic injury is unknown; mid-zonal necrosis has been described in low-flow hypoxia, ATP depletion and oxidative stress of marginally oxygenated cells at the border between anoxic and normoxic cells. Eosinophilic degeneration with condensed nuclear chromatin (Councilman bodies), indicative of apoptosis, characterizes hepatocyte injury rather than the ballooning and rarefaction necrosis seen in hepatitis caused by other viruses. Inflammatory changes are minimal and persons who survive YF do not develop scarring or cirrhosis due to this infection. Eosinophilic degeneration without inflammation, along with fatty change of renal tubular epithelium, also characterizes renal pathology. Focal degeneration may be present in myocardial cells. Lymphoid follicles of lymph nodes and spleen show necrosis. The brain shows edema and petechial hemorrhage but viral invasion and encephalitis are rare. Decreased hepatic synthesis of clotting factors causes hemorrhagic manifestations.

The mediators of the profound shock of YF are unknown but cytokine dysregulation (systemic inflammatory response syndrome, SIRS) likely mediates this terminal stage as in other sepsis syndromes. The appearance of antibody and cellular responses coincides with onset of the 'period of intoxication', suggesting that immune clearance may be, in part, responsible for the cytokine storm events. Persons with fatal YF have elevated pro-inflammatory cytokines compared to persons with nonfatal cases of YF, resembling the profile seen in bacterial sepsis. Overall, these findings suggest that high levels of pro-inflammatory cytokines contribute to lethality.

Immune Responses

Prior to appearance of specific cytotoxic T-cells and immunoglobulins, innate immunity, comprised of natural killer (NK) cells, interferons (IFNs), and other pro-inflammatory cytokines, play a significant role in limiting viral replication during early infection. NK cells recognize and lyse cells displaying viral antigens; secrete IFN-α and pro-inflammatory cytokines that have direct antiviral activity; activate DCs and macrophages; and promote a Th1 adaptive immune response. YFV antigens directly activate DCs via type I IFN signal transduction and Toll-like receptors. Through Toll-like receptor activation, pro-inflammatory molecules (e.g., interleukins IL1-β, IL2, IL6, IL8, IL12) are expressed and further activate NK cells. This robust innate response to YFV likely underlies the rapid, strong, and durable adaptive responses to this virus. Flaviviruses have evolved weak mechanisms for avoiding these innate responses, including blocking the IFN signal transducer pathways by NS2A and NS4B. Those patients with a poor outcome may develop signs of a dysregulated pro-inflammatory cytokine response (SIRS).

Seven to ten days after infection, a specific immune response is detectable when immunoglobulin M (IgM; enzyme-linked immunosorbent assay, ELISA), hemagglutination-inhibiting, and neutralizing antibodies begin to appear. IgM antibodies peak during the second week and usually decline rapidly over the next 30–60 days while neutralizing antibody continues to increase. When YFV represents the patient's first flavivirus infection, the magnitude of the IgM response is significantly greater than in persons with prior flavivirus exposure. Although little is known about cytolytic antibodies against viral proteins on the surface of infected cells, antibody-dependent cell-mediated cytotoxicity (ADCC), and cytotoxic T-cells,

these mechanisms, in addition to neutralizing antibody, presumably mediate clearance of primary infection. Based on immunologic studies of YFV vaccine recipients, neutralizing antibody generally peaks 4–6 weeks after infection but high titers of neutralizing antibodies persist for more than 10 years and provide complete protection against disease on reexposure to the virus. No documented case of a second clinical YFV infection has ever been reported. Although initial antibody response to infection is YFV antigen specific, with affinity maturation, specificity declines and cross-reactions with other flaviviruses develop during the subsequent several week of the immune response. Persons with prior heterologous flavivirus immunity develop broadly cross-reactive antibody responses during YFV infections. Previous infection with flaviviruses, such as Zika, dengue, or Wesselsbron viruses, provides partial cross-protection against YFV and may ameliorate the clinical severity of YF.

Prevention and Control

Domestic control of *Ae. aegypti* mosquitoes remains important but is difficult to sustain. Currently, the most effective approach to control of YF is by immunizing persons living in or traveling to endemic areas. 17D vaccine is the only strain currently used for human immunization against YFV. It is a live, attenuated vaccine produced in embryonated chicken eggs. 17D vaccines are not biologically cloned and are heterogeneous mixtures of multiple virion subpopulations ('genetic swarms'); differences in plaque size, oligonucleotide fingerprints, and nucleotide sequences have been found but do not appear to affect safety or efficacy. Currently, manufacturers in seven countries market YFV 17D vaccine. Three manufacturers in Brazil, France, and Senegal produce large amounts of vaccine for the Expanded Programme of Immunization and for mass vaccination campaigns. As of 2006, annual global vaccine production was approximately 60 million doses. Monath *et al.* thoroughly review the development, immune response, and efficacy of the 17D vaccine strain.

As of 2006, over 400 million persons have been immunized with YFV vaccines. Over roughly 70 years of use, 17D vaccines have been acknowledged as one of the safest and most effective live vaccines in use. Recently, however, close scrutiny has been brought to bear as clinical and histopathological evidence has emerged linking 17D vaccines to severe and previously unrecognized adverse events, including viscerotropic disease closely resembling that caused by wild-type YFV. Although rare mutational events in 17D vaccine virus during replication in the host can alter pathogenicity, these recently reported serious adverse events were not associated with either mutations that change virulence or tropism of the virus or selection of virulent variants *in vivo*. Investigations suggest that host susceptibility, rather than a change in the virus, is responsible for these serious, adverse events. Advanced age and thymic disease appear to be risk factors for development of vaccine-associated viscerotropic disease. The incidence of this complication, which carries a case–fatality rate of approximately 50%, is believed to be 1:400 000.

Glossary

Antennal gland Complex excretory glands located behind the eyes on antenna on the head of decapods.

Hepatopancreas An organ of the digestive tract of arthropods and fish that provides the functions which are performed separately by the liver and pancreas in mammals.

Lymphoid organ Also known as the Oka organ, a component of the hematopoeitic system of penaeid shrimp consisting of lymphoid cells around the two subgastric arteries.
Pseudoknot A complex folded structure in an RNA molecule.
Slippery sequence A nucleotide sequence at which ribosomal slippage can occur during translation to cause a change in the reading frame.

Introduction

Yellow head virus (YHV) is a pathogen of the black tiger shrimp (prawn), *Penaeus monodon*, which is one of the world's major aquaculture species. Yellow head disease was first reported in central Thailand in 1990 from which it spread rapidly along the eastern and western coasts of the Gulf of Thailand to southern farming regions. Outbreaks of yellow head disease have since been reported from most of the major shrimp farming countries in Asia. It is suspected that the YHV (rather than monodon baculovirus, which is not usually pathogenic for juvenile shrimp) may have previously caused the crash of the shrimp farming industry in Taiwan during the late 1980s. Mortalities usually occur during the mid-late stages of grow-out in ponds with complete crop loss commonly occurring within 3 days of the first signs of disease. YHV is one genotype in a complex of closely related viruses infecting black tiger shrimp. Other genotypes include gill-associated virus (GAV) which has been associated with relatively less severe forms of disease in farmed shrimp in Australia, and at least four other genotypes for which no disease association has yet been established. YHV and the other genotypes are endemic throughout the Indo-Pacific region, occurring commonly as low-level chronic infections in healthy shrimp.

Taxonomy and Classification

YHV is a positive-sense single-stranded RNA (ssRNA) virus that shares aspects of genome organization, replication, and transcription with coronaviruses, toroviruses, and arteriviruses with which it is classified in the order *Nidovirales*. In 2002, the International Committee on Taxonomy of Viruses (ICTV) established the genus O*kavirus* in the new family *Roniviridae* to accommodate YHV and closely related GAV. *Okavirus* is derived from the Oka or lymphoid organ of penaeid shrimp in which the virus is commonly detected; *Roniviridae* is derived from the sigla rod-shaped nidovirus. *Gill-associated virus* was assigned as the type species of the genus because its biological and molecular characterization were more complete. YHV is currently classified as a member of the species *Gill-associated virus*. No virus other than those described in the yellow head complex is currently assigned to the *Roniviridae* but several viruses with similar morphology have been reported in crabs and fish. Roniviruses are the only members of the order *Nidovirales* that are currently known to infect invertebrates.

Virion Structure and Morphology

YHV virions are rod-shaped, enveloped particles (~50 nm × ~175 nm) with prominent diffuse spikes (~8 nm × ~11 nm) projecting from the surface (**Figure 1(a)**). Internal helical nucleocapsids are approximately 25 nm in diameter and have a periodicity of 5–7 nm. Filamentous nucleocapsid precursors, approximately 15 nm in diameter and of variable length (~80–450 nm), are observed in the cytoplasm, sometimes densely packed in paracrystalline arrays (**Figure 1(b)**). Nucleocapsids acquire trilamellar lipid envelopes by budding through membranes into intracytoplasmic vesicles or at the cell surface (**Figure 1(c)**). It has been reported that long nucleocapsid precursors generate elongated, enveloped structures that subsequently fragment into mature virions. The morphology of GAV virions is indistinguishable from that of YHV.

YHV virions contain a polyadenylated 26.6 kDa (+) ssRNA genome and three structural proteins. The nucleoprotein (p20) is a highly hydrophilic, basic protein that complexes with the genomic RNA in nucleocapsids. Transmembrane glycoproteins gp64 and gp116 are components of the envelope that form the visible projections on the virion surface. YHV infectivity can be at least partially neutralized by antibody to gp116 but not by antibody to gp64. It is reported that gp116 docks with a 65 kDa cell membrane protein (pmYRP65) that mediates YHV entry into susceptible shrimp cells. Knockdown of pmYRP65 expression has been reported to totally abrogate susceptibility of shrimp cells to YHV infection.

Genome Organization and Transcription Strategy

The 26 662 nt YHV genome comprises four long open reading frames (ORFs) designated ORF1a, ORF1b, ORF2, and ORF3 (**Figure 2**). ORF1a (12 216 nt) and ORF1b (7887 nt) encode all of the elements of a large replicase complex. ORF1a encodes a 4072 aa polyprotein (pp1a) that contains a 3C-like cysteine protease catalytic domain flanked by putative transmembrane domains. The pp1a protease has autolytic activity and appears to be involved in processing the replicase polyproteins. ORF1b overlaps ORF1a by 37 nt. Expression of ORF1b requires

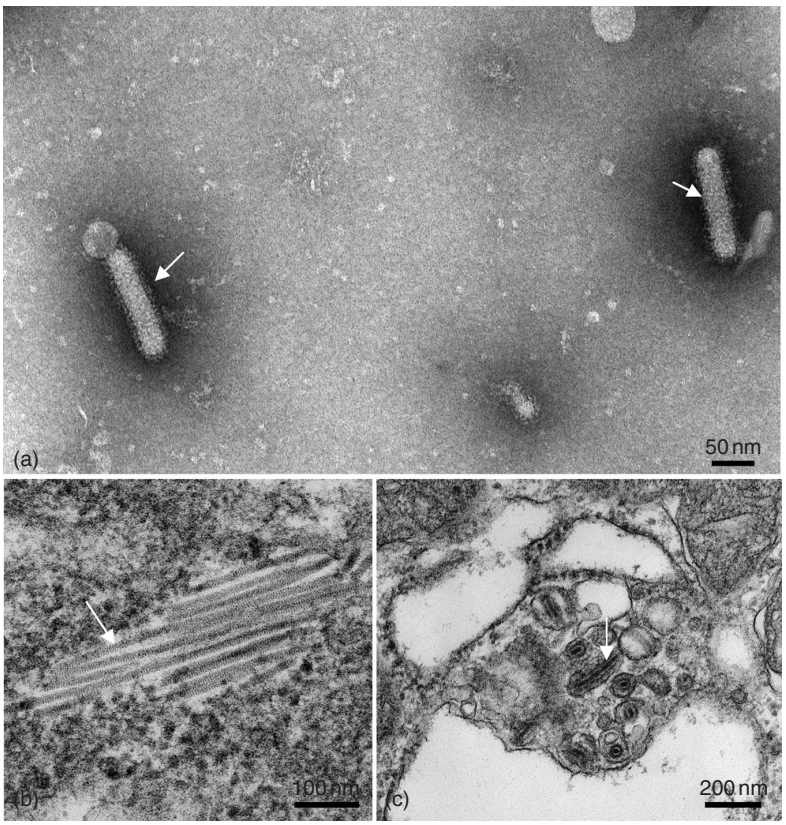

Figure 1 Transmission electron micrographs of YHV. (a) Image of virions stained with heavy metal salts showing the external appearance of the enveloped particles (arrows). (b) Image of an ultrathin section of helical nucleocapsids (arrow) within the gill of an infected shrimp. (c) Image of an ultrathin section of virions (arrow) within the gill of an infected shrimp. Kindly provided by Dr. Alex Hyatt, CSIRO, Australian Animal Health Laboratory, Geelong, Australia.

a −1 ribosomal frameshift at a slippery sequence (AAAUUUU) near a complex pseudoknot structure in the mRNA. The extended 6688 aa polyprotein (pp1ab) contains RNA-dependent RNA polymerase (RdRp), multinuclear zinc-binding (ZBD), helicase (HEL), 3′-5′ exoribonuclease (ExoN), uridylate-specific endoribonuclease (NendoU), ribose-2′-*O*-methyltransferase (O-MT) catalytic domains, and other cysteine/histidine-rich domains that are conserved in pp1ab of other nidoviruses. ORF2 encodes the 146 aa nucleocapsid protein (p20). Roniviruses are unique among known nidoviruses in that the nucleocapsid protein gene is located upstream rather than downstream of the glycoprotein genes. ORF3 encodes a 1666 aa polyglycoprotein that is processed to generate virion envelope glycoproteins gp64 and gp116. Proteolytic cleavage of ORF3 occurs at two [Ala-X-Ala] motifs immediately following predicted transmembrane domains that appear to function as signal peptides. The cleavage also generates a 228 aa (~22 kDa) protein that contains triple membrane-spanning domains and resembles M-proteins in coronaviruses. The YHV M-like protein appears to be present in infected cells at relatively low levels. The YHV genome also features significant noncoding regions, including a 71 nt untranslated region (UTR) at the 5′-terminus, a 352 nt UTR between ORF1b and ORF2, and a 54 nt UTR between ORF2 and ORF3. The 677 nt region between ORF3 and the 3′-poly[A] tail contains no long ORFs (>65 nt) and so also appears to be a long UTR (**Figure 2**).

Much of our understanding of YHV molecular biology has been obtained by comparison with closely related GAV. The 26 235 nt GAV genome is similar in structural organization to YHV, varying principally in the size and structure of the UTRs. In GAV, the ORF1b–ORF2 UTR comprises only 93 nt. The 638 nt region downstream of GAV ORF3 encodes a 252 nt ORF (ORF4) that has potential to express an unidentified 83 aa polypeptide with a deduced molecular weight ~9.2 kDa. A short ORF in the corresponding region of the YHV genome is truncated with a termination codon after only 20 aa and is unlikely to be expressed. Like other nidoviruses, the GAV genome is transcribed as a nested set of 3′-co-terminal mRNAs comprising the full-length genome and two subgenomic messenger RNAs (sg mRNAs) that initiate at conserved

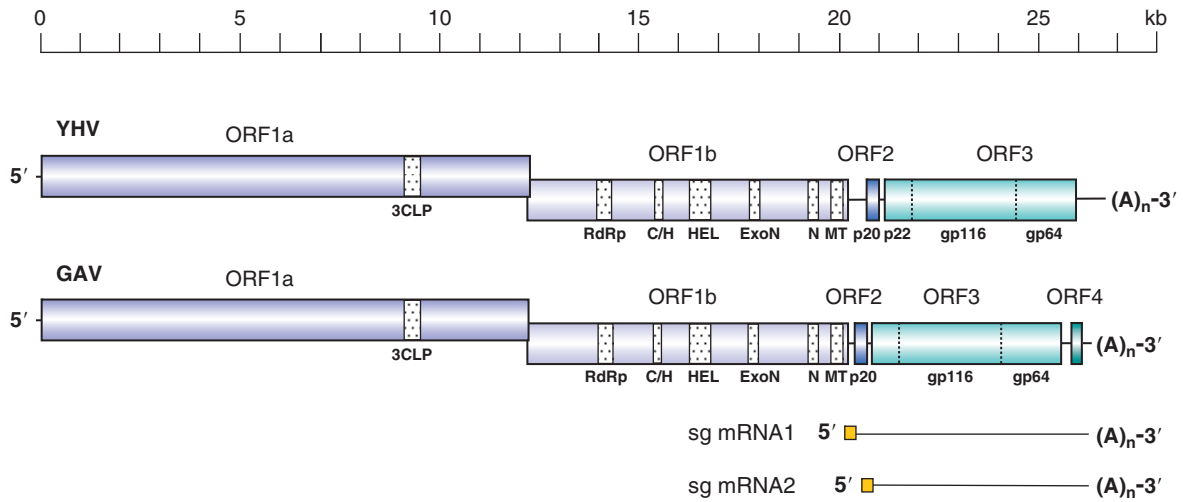

Figure 2 Genome organization of YHV and GAV indicating the locations of subgenomic mRNAs (sg mRNA1 and sg mRNA2) and functional domains in ORF1a (3CLP) and ORF1b (RdRp, C/H, HEL, ExoN, N, and MT). Also indicated are proteolytic cleavage sites in the ORF3 polyprotein that is processed post-translation to generate triple-membrane-spanning protein (p22) and transmembrane glycoproteins (gp116 and gp64).

transcription-regulating sequences (TRSs) in noncoding regions immediately upstream of ORF2 and ORF3. However, unlike coronaviruses and arteriviruses, conserved GAV (and YHV) TRSs are not present in the 5′-UTR of genomic RNA and so do not mediate splicing of common 5′-leader sequences on to the sg mRNAs. Sequences with partial identity to the conserved ORF2 and ORF3 TRSs occur upstream of GAV ORF4 (and the truncated YHV ORF4) but these do not appear to be functional.

Geographic Distribution and Host Range

Surveys for the presence of viral genomic RNA have indicated that YHV and other genotypes in the complex are endemic in black tiger shrimp populations across its natural geographic range throughout the Indo-Pacific. Yellow head disease has been reported in farmed tiger shrimp from Thailand, Taiwan, China, the Philippines, Vietnam, Malaysia, Indonesia, India, Sri Lanka, and Madagascar. Although natural infection and disease have been reported only in black tiger shrimp and kuruma shrimp (*Marsupenaeus japonicus*), YHV can cause high rates of mortality following experimental infection of most other farmed marine shrimp species, including Pacific white shrimp (*Litopenaeus vannamei*), Pacific blue shrimp (*Litopenaeus stylirostris*), brown tiger shrimp (*Penaeus esculentus*), white banana shrimp (*Fenneropenaeus merguiensis*), white shrimp (*Litopenaeus setiferus*), brown shrimp (*Farfantepenaeus aztecus*), hopper and brown-spotted shrimp (*Farfantepenaeus duorarum*), red endeavour prawn (*Metapenaeus ensis*), and Jungas shrimp (*Metapenaeus affinis*). Some species of palemonid shrimp and krill are also susceptible to experimental infection. Crabs appear to be refractory to YHV infection and disease.

GAV has been associated with a less-aggressive disease of juvenile black tiger shrimp in Australia called mid-crop mortality syndrome. However, several other viruses have also been detected in shrimp with this condition and the etiology remains uncertain. GAV does cause disease and mortalities following experimental infection of several farmed shrimp species, including black tiger, brown tiger, and kuruma shrimp. GAV and other genotypes in the YHV complex have also been detected in healthy black tiger shrimp from Taiwan, the Philippines, Malaysia, Brunei, Indonesia, Vietnam, Thailand, India, Mozambique, and Fiji. A very high prevalence of GAV infection has been reported in healthy black tiger shrimp from eastern Australia. Evidence of GAV infection has also been detected in mud crab (*Scylla serrata*) in an experimental aquaculture facility.

Pathology

Shrimp are susceptible to YHV infection from late postlarval stages but mass mortality in ponds usually occurs in early-to-late juvenile stages. Disease and mortalities usually occur within 2–4 days of a period of exceptionally high feeding activity followed by an abrupt cessation of feeding. Moribund shrimp congregate at pond edges near the surface and may exhibit a bleached overall appearance and discoloration of the cephalothorax caused by yellowing of the underlying hepatopancreas.

YHV infects tissues of ectodermal and mesodermal origin, including lymphoid organ, hemocytes, hematopoeitic tissue, gill lamellae, and spongy connective tissue of the subcutis, gut, antennal gland, gonads, nerve tracts, and ganglia. In severe infections, there is a generalized cell degeneration with prominent nuclear condensation, pyknosis and karyorrhexis, and basophilic, perinuclear cytoplasmic inclusions in affected tissues. There is evidence of apoptosis, including chromatin condensation and DNA fragmentation, in hemocytes, lymphoid organ, and gill tissues and it has been suggested that widespread apoptosis rather than necrosis is the cause of disease and mortalities.

YHV, GAV, and other viruses in the yellow head complex can also occur as low-level chronic infections in apparently healthy shrimp. Chronic infections have been observed in shrimp of all life stages collected from hatcheries and farms, and in the survivors of experimental infection. For GAV, the progression of infection following experimental challenge has been shown to be dose related. Shrimp infected with a high dose of GAV progress rapidly to disease with high viral loads and typical pathology leading to mortalities. Shrimp infected with a low dose do not develop disease and the virus persists as a low-level infection for at least 60 days. There is also evidence that stress can lead to rapid increases in viral load. For YHV, the onset of disease has been associated with the stress of molting. During chronic infections, there is little histopathology other than the accumulation of partitioned foci of cells with hypertrophic nuclei (spheroid bodies) in the lymphoid organ. Spheroid bodies appear to form in shrimp as part of a nonspecific defense mechanism for clearance of infectious agents and other foreign bodies.

Host Response to Infection

As invertebrates, shrimp lack antibodies, cytokines, T-lymphocytes, and other powerful components of the vertebrate immune system that allow a specific adaptive response to viral infection, clearance of virus and infected cells, and long-term immunological memory. There is also no evidence in shrimp of interferon, natural killer (NK) cells, or other key components of the vertebrate natural immune system that allow an immediate nonspecific defense against viruses. Nevertheless, shrimp do appear to have a capacity to respond to viral infection and highly pathogenic viruses are commonly present as low-level chronic infections in apparently healthy shrimp. For YHV, there is no evidence of an inflammatory response at the primary sites of infection. However, YHV accumulates in spheroid bodies in the lymphoid organ during chronic persistent infections, and it is thought that the lymphoid organ has an important role in filtering granulated hemocytes and the clearance of viruses from infected shrimp. It has been reported that cells within lymphoid organ spheroids become apoptotic during infection and may be cleared during molting. Apoptotic cells have been observed in lymphoid organs, hemocytes, and gills during acute YHV infections in what appears to be a fundamental host defensive reaction. It has also been reported that double-stranded RNA (dsRNA) corresponding to sequences in viral replicase and glycoprotein genes specifically inhibits YHV infection *in vitro* and *in vivo*, suggesting that RNA interference may play a role in the host response to infection.

Transmission

The natural transmission cycle of YHV has not been studied in detail. Experimentally, YHV infection and disease can be transmitted horizontally by injection, ingestion of infected tissue, immersion in membrane-filtered tissue extracts, or by cohabitation with infected shrimp. Transmission of disease by ingestion has been demonstrated from the late postlarval stages onward. Transmission has also been demonstrated by injection of black tiger shrimp with extracts of paste shrimp (*Acetes* sp.) and mysid shrimp (*Palaemon styliferus*) collected from infected ponds. For GAV, there is evidence that horizontal transmission can occur from chronically infected shrimp in the absence of disease.

There is no direct evidence of vertical transmission of YHV but it can be detected as a chronic infection in broodstock prior to spawning, and polymerase chain reaction (PCR) screening to eliminate infected broodstock and seed is increasingly being used to reduce risks of yellow head disease in ponds. GAV has been detected in spermatophores and mature ovarian tissue of broodstock, and in fertilized eggs and nauplii spawned from infected females. Examination by electron microscopy has revealed virions in seminal fluid but not in sperm cells. Artificial insemination of infected broodstock has shown that vertical transmission occurs efficiently from both male and female parents. Transmission is probably by surface contamination or infection of tissue surrounding the fertilized egg. The high prevalence of yellow head complex viruses in postlarvae collected from hatcheries in Australia and several Asian countries supports the view that vertical transmission has an important role in the infection cycle of all genotypes, particularly during propagation for aquaculture.

Genetic Diversity

YHV is one of several closely related genotypes that have been detected in black tiger shrimp in the Indo-Pacific region. Analysis of nucleotide and deduced amino

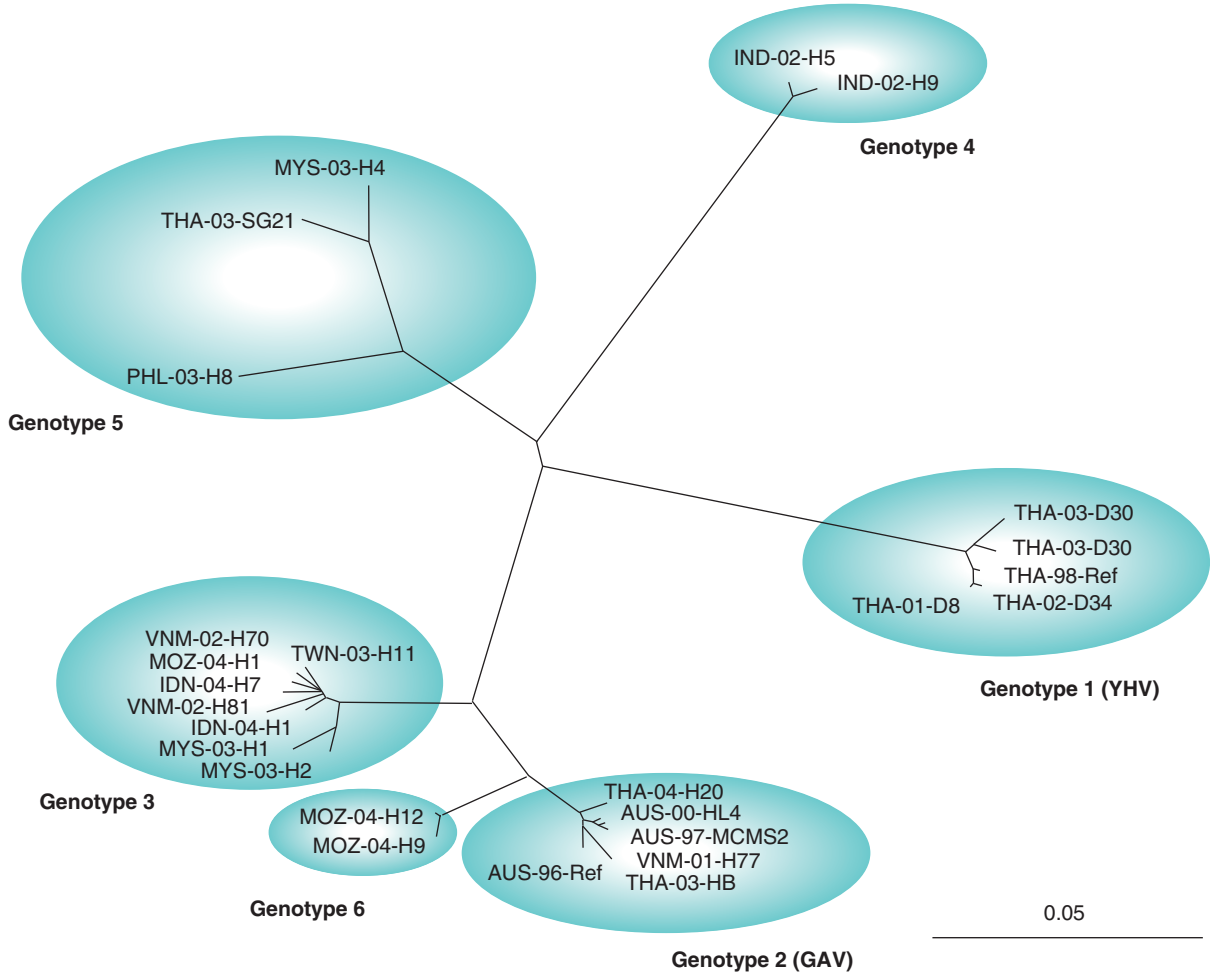

Figure 3 Phylogenetic tree constructed from an alignment of nucleotide sequences obtained from 26 viruses detected in *Penaeus monodon* shrimp from the Indo-Pacific region. The sequences correspond to a 671 nucleotide region of the ORF1b gene encompassing elements of the HEL domain. The alignment illustrates the six known genotypes in the yellow head complex including YHV (genotype 1), GAV (genotype 2), and four other genotypes (genotypes 3, 4, 5, and 6) that have been detected only in healthy shrimp. The viruses were obtained from shrimp collected in India (IND), Malaysia (MYS), Thailand (THA), the Philippines (PHL), Australia (AUS), Vietnam (VNM), Mozambique (MOZ), Indonesia (IDN), and Taiwan (TWN) between 1997 and 2004. Sequences kindly provided by Mrs Priyanjalie Wijegoonawardane, CSIRO Livestock Industries, St. Lucia, Australia.

acid sequences in a relatively conserved region of the ORF1b gene has identified at least six distinct genetic lineages in the complex (**Figure 3**). In pairwise alignments, nucleotide sequence identity between consensus sequences representing each genotype ranges from 80.3% to 96.5%. Variation within genotypes is generally low, with nucleotide sequence identities between isolates in the range 97.1–100%, except genotype 5 for which three available isolates have been reported to share 93.0–97.1% identity.

YHV (genotype 1) is the only genotype that has been detected in shrimp with typical signs of yellow head disease. Although the disease has been reported from many sites in Asia, isolates are currently available only from Thailand and Taiwan. Genotype 1 is the most distantly related to other lineages and appears to occur less commonly than other genotypes in healthy shrimp. GAV (genotype 2) is the only other lineage known to be associated with disease of any form. Analysis of complete genome sequences of prototype strains of YHV and GAV indicates similar nucleotide sequence identities for ORF1a (79.7%), ORF1b (82.3%), ORF2 (81.0%), and a slightly lower level of identity for ORF3 (73.2%). Amino-acid-sequence identities between YHV and GAV proteins are similar for the replicase pp1ab (84.9%), nucleoprotein p20 (84.4%), and glycoprotein gp64 (83.9%), and lower for the M-like protein p22 (74.8%) and glycoprotein gp116 (71.7%).

GAV has been detected in black tiger shrimp from Australia, Vietnam, and Thailand. Phylogenetic analysis

of sequences analyzed to date suggests that all isolates may have originated from translocated Australian shrimp. Genotype 3 has been detected to date in Taiwan, Vietnam, Indonesia, Malaysia, Thailand, and Mozambique. It appears to be the most widely distributed and most frequently detected genotype. Genotype 4 has been detected only in India. Genotype 5 has been detected in the Philippines, Malaysia, and Thailand. As indicated above, genotype 5 is genetically the most diverse genotype and may be split into three distinct lineages as more isolates become available. Genotype 6 has been detected only in Mozambique.

Assignment of these genotypes has been based primarily on comparisons of sequences in a conserved region of the ORF1b gene. Analysis of nucleotide sequences in the 5′-terminal region of the ORF3 polyglycoprotein gene indicates more genetic variability and suggests that genetic recombination is contributing to diversity in the complex. Of 24 isolates examined recently, almost one-third were assigned to different genotypes in comparative phylogenetic analyses of nucleotide sequences in the ORF1b and ORF3 regions. Genetic recombination is a phenomenon known to occur commonly in other nidoviruses. It appears that the vast international trade in live shrimp broodstock and seed for aquaculture is providing adequate opportunities for recombination and diversification of the gene pool. This appears to confound the assignment of coherent genetic lineages and may have significant consequences for both the emergence and definitive diagnosis of disease.

Diagnosis and Disease Management

Gross clinical signs of YHV infection including yellowing of the carapace and erratic swimming behavior are not observed consistently and are not sufficiently pathognonomic to be useful for disease diagnosis. Histologically, moderate to large numbers of basophilic, spherical, cytoplasmic inclusions in tissues of ectodermal and mesodermal origin are indications of YHV infection and can be used for presumptive diagnosis. Confirmatory diagnosis of yellow head disease requires the use of electron microscopy or molecular methods such as the reverse transcriptase-polymerase chain reaction (RT-PCR) or *in situ* hybridization assays. Antibody-based tests such as western blotting and dot-blot nitrocellulose enzyme immunoassay (NC-EIA) are also available. Low-level chronic infections with YHV and other genotypes can be detected by nested RT-PCR or other highly sensitive molecular genetic tests such as real-time PCR or loop-mediated isothermal amplification (LAMP). Accurate genotype assignment can only be achieved by PCR, sequence analysis, and comparison with sequences of other known genotypes.

No effective vaccines or therapeutics are currently available for the control of YHV and no genetically resistant shrimp stocks have been reported yet. Disease management is primarily through pathogen exclusion by PCR screening of broodstock and/or seed, the application of on-farm biosecurity and sanitary measures, and stress reduction by careful management of water quality during grow-out.

Current Status

Key aspects of the biology of YHV infection are yet to be resolved and yellow head continues to be a disease of concern to aquaculture farmers. No direct link has been demonstrated between the presence of virus in infected broodstock and the appearance of disease on farms. Assumptions about vertical transmission come by analogy with GAV and may well be accurate. However, the prevalence of YHV in healthy shrimp appears to be far lower than for GAV and other genotypes, and it is unclear how it maintains a cycle of natural infection. It is possible that YHV is commonly introduced to ponds in healthy wild shrimp or other carrier crustaceans but surveys to date have not revealed a likely source. The host–viral interaction during the chronic phase of infection, the transition from chronic to acute phases, and the role of stress in disease emergence are also poorly understood, and there is little understanding of the molecular basis of virulence variations between YHV and other genotypes. A more comprehensive study of the sources of YHV infection and host and/or environmental factors leading to emergence of yellow head disease should be conducted. Emerging capabilities in shrimp genomics and proteomics will greatly facilitate this work.

There is an emerging understanding of RNA interference (RNAi) as a potentially powerful mechanism for the control of viral diseases. Inhibition of YHV infection in primary lymphoid organ cell culture has been demonstrated by treatment with dsRNA corresponding to YHV protease, polymerase, and helicase domains. Injection of shrimp with protease domain dsRNA has also been shown to inhibit YHV replication and mortalities. Knockdown of the shrimp dicer-1 endoribonuclease gene expression has demonstrated that the antiviral effects of dsRNA are caused by RNAi. RNAi technology has useful applications in studies of the molecular biology of YHV infection and, if delivered cost-effectively, could potentially find commercial application in the management of yellow head disease.

Roniviruses are also seen as important links in understanding the evolutionary biology of (+) ssRNA viruses. Considerations of virion structure and the size, complexity and structural organization of the genome suggest that roniviruses form a genetic lineage ancestral to

coronaviruses and toroviruses. Studies of the ronivirus 3C-like cysteine protease encoded in ORF1a have also revealed structural similarities to coronaviruses in the catalytic site but substrate specificity and binding sites are more similar to those of potyviruses, suggesting that they bridge the gap between these distantly related proteases. A pseudoknot structure and slippery sequence at the ribosomal frameshift site is also distinct from the H-type structures characteristic of many vertebrate nidoviruses. Further molecular studies of ronivirus structure and function should provide insights into the evolution of these unusual viruses.

Zoonoses

J E Osorio and T M Yuill, University of Wisconsin, Madison, WI, USA

© 2008 Elsevier Ltd. All rights reserved.

Introduction

Zoonoses are diseases transmissible from vertebrate animals, other than humans, to people. Mammals, birds, reptiles, and probably amphibians are reservoirs or amplifier hosts for these viral zoonoses. Frequently, these viruses cause little or no overt disease in their nonhuman vertebrate hosts. Some zoonotic viruses have very limited host ranges; others may infect a wide range of vertebrates. Human infection may vary from unapparent to fatal disease. Both new and old viral zoonoses are especially important in emerging and re-emerging virus diseases. Transmission of zoonotic viruses may occur by a variety of routes. They include: 'direct' (rabies) or 'indirect' (hantavirus) contact; 'nosocomial' (arenavirus and filovirus); 'aerosol transmission' (SARS coronavirus); 'vertical' (*in utero*) (arenaviruses); and 'vector- or arthropod-borne' (yellow fever, YF). Viral zoonotic diseases occur on every continent except, perhaps Antarctica. Some are found around the world, in a variety of ecological settings. Others are found only in very limited ecologic and geographic foci. Although hundreds of viruses are zoonotic, the importance of many of these viruses has not yet been established. Some of the more important viral zoonoses will be discussed briefly.

Rabies Virus

Rabies is one of the oldest reported zoonoses. Rabies virus infection causes nervous system disease that ends in death. Animals can become infected without nervous system disease, develop antibodies, and survive, but play no role in transmission. Classical rabies is found all around the world except in Antarctica, Britain, the Hawaiian Islands, Australia, and New Zealand. Transmission occurs by the bite of an infected animal. Aerosol (droplet) transmission is rare. Dogs and cats are the main reservoirs in tropical developing countries where more than 99% of all human cases occur. In industrialized countries, wild mammals are the main reservoirs and the species involved vary from region to region. The principal species are as follows: in North America, skunks, raccoons, and foxes; in Europe, foxes; and in the Caribbean, mongooses. Bats in all enzootic regions harbor rabies with vampire bats especially important in the Neotropics, where they transmit rabies to cattle, horses, and other domestic animals, and, occasionally, to humans. Rabies virus is classified in the genus *Lyssavirus* of the family *Rhabdoviridae*. Genetic relationships between rabies isolates from different species and geographic areas have been established by genomic sequence analysis (**Table 1**).

Diagnosis is based on characteristic altered behavior of infected mammals, confirmed by either isolation of virus; demonstration of intracellular antigen by immunofluorescence; or of virus genomic sequences. Postexposure treatment is accomplished by thorough washing of the bite wound, administration of hyperimmune serum or globulin, and administration of antirabies vaccine. Dogs and cats in enzootic areas should be vaccinated. Other domestic animals and humans at high risk should also be vaccinated. Vaccination campaigns of free-ranging red fox populations in Europe and raccoons and coyotes in the USA have been carried out by oral administration of recombinant vaccinia-vectored vaccines in bait.

Hantavirus Hemorrhagic Fevers and Pulmonary Syndrome Viruses

Hantaviruses belong to the genus *Hantavirus* of the family *Bunyaviridae*. In the Americas, hantavirus can cause hantavirus pulmonary syndrome (HPS), an infectious disease typically characterized by fever, myalgia, and headache and followed by dyspnea, noncardiogenic pulmonary edema, hypotension, and shock. HPS has also been reported and confirmed in seven countries in South America: Argentina, Bolivia, Brazil, Chile, Paraguay, Uruguay, and Panama (**Table 2**). Hantaviruses are harbored by wild rodents which often live in close association with humans. Virus

Table 1 Rabies and related lyssaviruses

Virus name	*Lyssavirus genotype*	*Location*	*Host*
Rabies	1	Worldwide	Many wild and domestic mammals
Lagos bat	2	Africa	Bats, water mongoose (but no human disease)
Mokola	3	Africa	Several terrestrial mammals
Duvenhage	4	Africa	Bats
European bat-1	5	Europe	Bats
European bat-2	6	Europe	Bats
Australian bat	7	Australia	Bats
Aravan	New, proposed	Kyrgystan	Bats
Khujand	New, proposed	Tajikistan	Bats
Irkut	New, proposed	Russia	Bats
West Caucasian bat	New, proposed	Russia	Bats

Table 2 Hantaviruses that cause human disease

Virus name	*Distribution*	*Rodent host*	*Human disease*
Hantaan	Asia, Europe	*Apodemus agrarius*	Hemorrhagic fever with renal syndrome
Seoul	Worldwide	*Rattus* spp.	Hemorrhagic fever with renal syndrome
Dobrava-Belgrade	Europe, Middle East	*Apodemus flavicollis*	Hemorrhagic fever with renal syndrome
Puumala	Europe, Asia	*Clethrionomys glareolus*	Hemorrhagic fever with renal syndrome
Sin Nombre	North America	*Peromyscus maniculatus*	Pulmonary syndrome
New York	North America	*Peromyscus leucopus*	Pulmonary syndrome
Bayou	North America	*Oryzomys palustris*	Pulmonary syndrome
Black Creek Canal	North America	*Sigmodon hispidus*	Pulmonary syndrome
Andes	South America	*Oligoryzomys longicaudatus*	Pulmonary syndrome
Hu39694	South America	Unknown	Pulmonary syndrome
Juquitiba	South America	Unknown	Pulmonary syndrome
Laguna Negra	South America	*Calomys laucha*	Pulmonary syndrome
Lechiguanas	South America	*Calomys laucha*	Pulmonary sybdrome
Oran	South America	*Oligoryzomys longicaudatus*	Pulmonary syndrome
Choclo	Panama	*Zygodontomys brevicauda*	Pulmonary syndrome
Monogahela	North America	*Peromyscus maniculatus nubiterrae*	Pulmonary syndrome
Bermejo	South America	*Oligoryzomys chacoensis*	Pulmonary syndrome
Central Plata	South America	*Oligoryzomys flavescens*	Pulmonary syndrome
Araraquara	South America	*Bolomys lasiurus*	Pulmonary syndrome

is shed in urine and other excreta. Outbreaks of HPS have been associated with ecological changes and invasion of human habitations by expanding rodent populations. Diagnosis has been complicated by the lack of efficient and sensitive isolation and serological methods. Rodent control and avoidance of exposure to rodent excreta, especially in dust, are the only methods available currently for prevention of transmission to humans.

Arenavirus Hemorrhagic Fever Viruses

Arenaviruses are transmitted by the same kind of rodents that carry hantaviruses. They can also cause hemorrhagic fevers and, even though the prototype of this family has been long known (lymphocytic choriomeningitis virus, LCMV), viruses within this family are still being discovered. They produce human diseases in the Old World (Lassa fever in Africa) and New World (Junin, Machupo, and, later on, Guanarito and Sabia in South America). There are about 22 different arenaviruses in the Americas, but only four are associated with significant human disease. These pathogenic arenaviruses establish persistent infection in their rodent hosts, and the virus is shed in urine, infecting humans who live in close contact with these contaminated environments. Lassa fever is also transmitted nosocomially in rural hospitals to other people in contact with blood from viremic patients. Control of these diseases is attempted mainly by reduction of rodent populations. A live, attenuated vaccine has been developed for Argentine hemorrhagic fever, and a vaccinia-vectored vaccine has been developed for Lassa fever. Ribavirin is effective for treating arenavirus infection if administered early in the course of infection.

YF Virus

YF is a flavivirus that causes hemorrhagic disease with severe liver damage and death in up to half of the most acute cases. Humans or primates transport the virus from its sylvan cycle in forested areas to rural or urban areas, where other vector mosquitoes transmit it. YF remains a disease of significant public health importance, with an estimated 200 000 cases and 30 000 deaths annually. The disease is endemic in tropical regions of Africa and South America; nearly 90% of YF cases and deaths occur in Africa. It is a significant hazard to unvaccinated travelers to these endemic areas. Re-establishment of the major urban vector, *Aedes aegypti*, the recent spread of the Asian tiger mosquito (*Ae. albopictus*) as well as the rise in air travel has increased the risk of introduction and spread of the disease. YF is an acute infectious disease characterized by sudden onset with a two-phase development, separated by a short period of remission. The clinical spectrum of YF varies from very mild, nonspecific, febrile illness to a fulminating, sometimes fatal disease with pathognomic features. In severe cases, jaundice, bleeding diathesis, with hepatorenal involvement is common. There is no specific treatment for YF, making the management of YF patients extremely problematic. YF can be diagnosed by virus isolation, detection of circulating antigens, demonstration of a significant rise in specific YF virus antibodies, and microscopic detection of viral inclusion bodies or antigen in tissues taken at postmortem examination. Insecticide spraying and elimination of breeding sites in homes can be used for vector control in epidemic situations. Disease can be prevented in humans by vaccination.

West Nile Virus

West Nile virus (WNV) is an arthropod-borne RNA flavivirus that causes a mild infection to acute febrile disease with rash, and occasional encephalitis (mainly in the elderly) is produced in humans. The virus is widely spread, occurring from India and Pakistan westward through the Middle East and into Africa, and northward into Europe, the republics of the former USSR, and in the Western Hemisphere. WNV first appeared in North America in 1999 with an outbreak in New York City producing high mortality in crows and other birds. Subsequently, the virus has spread rapidly throughout North America, the Caribbean, Mexico, and into South America. WNV is now present in every state except Hawaii, and Alaska. It is believed that the NY99 virus has remained stable and unchanged. The ecology of WNV involves maintenance in a bird–mosquito–bird cycle and occasional infection of humans and horses. *Culex* spp. are the main vectors, and birds are the vertebrate hosts. There is no vaccine currently available for humans, although there is one for equine animals.

Chikungunya Virus

Chikungunya (CHIK) is an alphavirus of the family *Togaviridae* that has been responsible for acute febrile disease with rash and severe arthralgia in people in Africa and Asia. An outbreak of CHIK was reported on Reunion Island in March 2005 that resulted in >3500 confirmed cases and an estimated 250 000 suspected cases, affecting >25% of the island's inhabitants. CHIK virus is maintained in sylvan or savanna cycles involving wild primates and arboreal *Aedes* mosquitoes. In both Africa and Asia, the virus also has an urban cycle involving humans and *Ae. aegypti* mosquitoes that is more important from a public health standpoint.

Sindbis Virus

Sindbis (SIN) virus is one of the most widely distributed arthropod-borne viruses in the world, being found in Africa, Europe, Asia, and Australia. Disease in humans is usually mild, and is characterized by acute fever, with arthralgia, myalgia, and rash. There are periodic epidemics in Finland, where it is termed Podosta disease. SIN virus is maintained in wild bird populations, with transmission by *Culex* spp. mosquitoes. In Africa and the Middle East, SIN is often found in the same ecosystems where WN virus is being transmitted. The virus is an alphavirus of the *Togaviridae*. Phylogenetic analysis indicates that there is one major genetic cluster of western SIN virus strains in Africa and another in Australia and Asia. There is evidence of some geographic mixing of western strains of SIN virus that suggest long-distance transport via migrating birds. There is no vaccine available. Since many of the mosquito vectors breed in extensive rice fields, large-scale control would be expensive.

Crimean-Congo Hemorrhagic Fever Virus

Crimean-Congo hemorrhagic fever (CCHF) virus is very widely distributed, and is found from eastern Europe and the Crimean, eastward through the Middle East to western China, and southward through Africa to South Africa. CCHF is characterized by severe hemorrhagic fever with hepatitis, with case mortality of 10–50%. Maintenance of CCHF virus involves horizontal transmission from *Hyalomma* ticks to mammals, and vertical transmission in ticks through the eggs. *Hyalomma* ticks have also been found on birds migrating between Europe and Africa – a

mechanism for long-distance dispersal of the virus. Human CCHF cases have occurred in workers handling livestock and their products in Saudi Arabia and the United Arab Emirates which have been attributed to importation of infected cattle and their ticks from Somalia and the Sudan. There are no vaccine or tick control measures available. CCHF virus belongs to the genus *Nairovirus* of the *Bunyaviridae*. Genetic analysis indicates that reassortment and recombination occur in nature.

Sandfly Fever Viruses

Sandfly fever (Sicilian, Naples, and Toscana) viruses are endemic in the Mediterranean area. They cause acute febrile disease in humans, with occasional aseptic meningitis. In central Italy, Toscana virus (TOSV) caused one-third of previously undiagnosed cases of aseptic meningitis. There are at least two genetic lineages of TOSV – Spanish and Italian. The viruses are members of the genus *Phlebovirus* of the *Bunyaviridae*. They are transovarially and horizontally transmitted by phlebotomine sandflies. Wild mammals are presumed reservoirs.

Viruses Occurring in the Americas

Encephalitis Viruses

Venezuelan equine encephalitis (VEE) viruses are made up of a closely related complex of subtypes with several varieties, which have differing epidemiology, geographic distributions, and disease importance. The epizootic/epidemic (VEE, IAB, and IC) virus variants are of greatest concern. In equine animals, the virus causes acute encephalitis, and case fatality may approach 80%. Survivors may have serious neurological deficits. Although the case–fatality rate in humans is low (less than 1%), the large numbers of acutely infected people that occur during an epidemic may completely overwhelm the local health-care system. VEE, IAB, and IC viruses are maintained in northern South America, where they have periodically swept through Venezuela and Colombia in epidemic waves, with occasional extensions into Ecuador and massively through Central America into Mexico and South Texas. Epidemic spread depends on the availability of susceptible equine populations (the amplifying host) and abundant mosquito vectors of several species. The interepidemic maintenance systems remain undefined. There is evidence that the epizootic strains may arise by mutation of subtype ID enzootic virus. The enzootic strains are maintained in limited foci involving rodents and *Culex* (*Melanconion*) spp. mosquitoes from Florida to Argentina. With the exception of subtype IE, which has caused epizootics in horses in Mexico, these enzootic virus strains do not cause disease in equine animals, but can cause acute febrile illness in humans. The VEE complex viruses are in the genus *Alphavirus* of the *Togaviridae*. There is an effective live, attenuated vaccine for both human and equine use. Because the maintenance of equine herd immunity is costly, most animal health agencies do not carry out ongoing, intensive vaccination campaigns. Thus, the risk of reoccurrence of explosive outbreaks remains.

Eastern (EEE) and western (WEE) equine encephalitis viruses occur in epidemic form in North America, but have also been found in Central and South America. Generally, EEE is maintained in eastern North America but has caused scattered epizootics and cases in the Caribbean, and in Central and South America. EEE virus can be divided into a North American-Caribbean clade, an Amazon Basin clade, and a Trinidad, Venezuela, Guyana, Ecuador, and Argentina clade. During the past several years, there have been modest increases in several US states in the number of reported human cases of EEE. In North America, WEE occurs in western and prairie states and provinces and along the west coast. WEE has caused sporadic cases of encephalitis in equine animals, but not humans, in Argentina and Uruguay. Both involve wild birds and mosquito vectors, with spillover into equine population and humans, causing clinical encephalitis and death. Central nervous sequelae may occur among survivors. Effective vaccines are available commercially for equine animals, and experimental vaccines are used for laboratory personnel. Effective mosquito abatement to control vector populations has been carried out in the West for many years. Insecticide application is used for vector control in epidemic situations.

St. Louis encephalitis (SLE) virus occurs from Canada to Argentina and causes sporadic but extensive epidemics in the USA, with most epidemics occurring in the West, down the Ohio and Mississippi valleys into Texas, and in Florida. Wild passerine birds are amplifying hosts in North America, but in the Southeastern USA and the Neotropics mammals may play an epidemiologic role in virus maintenance and transmission. SLE virus is transmitted by *Culex* spp. mosquitoes in the USA. SLE virus is a flavivirus of the *Togaviridae*, and is closely related to Japanese encephalitis virus. In humans, SLE is characterized by febrile disease, with subsequent encephalitis or aseptic meningitis, and strikes older people more often than the young. Since no vaccine is available, SLE prevention and control relies on surveillance, vector control, and screening of dwelling windows and doors.

Powassan (POW) virus is a North American member of the flavivirus tick-borne encephalitis (TBE) complex. Although POW virus is widely distributed across the USA and Canada, and westward into far eastern Russia, disease (febrile, with encephalitis) has only been detected in the eastern states and provinces of North America. The transmission cycle involves small mammals and *Ixodes* ticks.

La Crosse (LAC) and other California serogroup encephalides are human pathogens in North America. Prior to the arrival of WNV, LACV was the most important cause of endemic arboviral encephalitis in the US, causing an estimated average of 80 cases per year, affecting mainly preschool-aged children. It is endemic in the Upper Midwest, but occasional cases occur elsewhere. Although fatality is uncommon, the disease is severe enough to cause prolonged hospitalization. LAC virus is maintained transovarially in treehole breeding by *Ochlerotatus* (formerly *Aedes*) *triseriatus* mosquitoes with horizontal transmission to small forest mammal reservoirs and to humans. The other California group viruses affecting people have similar epidemiologies, but do not cause disease as commonly. California encephalitis virus was isolated in California, and has occasionally caused human disease there. Snowshoe hare (SSH) virus occurs in the Northern USA and across Canada, and has caused human encephalitis in the eastern provinces. Jamestown Canyon (JC) virus is widely distributed across the USA, and has been shown to cause human disease, mainly in adults in the Midwest, and to infect deer. Like LAC virus, these other viruses have the same close epidemiological relationship with their *Ochlerotatus* vectors. These viruses are members of the California serogroup of the genus *Bunyavirus* of the family *Bunyaviridae*. SSH virus is an antigenic variant of LAC virus.

Colorado Tick Fever Virus

Colorado tick fever (CTF) is endemic in sagebrush–pine–juniper habitats of the higher elevations (over 1200 m) in the mountains of the western states and provinces of North America. Although seldom fatal, CTF can cause serious disease in humans (fever, chills, headache, retroorbital pain, photophobia, myalgia, abdominal pain, and generalized malaise) with prolonged convalescence. CTF may present as hemorrhagic or central nervous system disease, and is most severe in preadolescent children. Males are infected over twice as frequently as are females. The virus is transmitted by and overwinters in *Dermacentor andersoni*. Wild rodents are the vertebrate hosts, and develop a prolonged viremia. CTF virus is classified in the genus *Coltivirus* of the family *Reoviridae* and is serologically related to Eyach virus from Germany. Avoidance of tick bites is the main preventive measure available, but control of rodents and the ticks that inhabit their burrows can be applied in foci of virus maintenance in the field.

Vesicular Stomatitis Virus

Vesicular stomatitis (VS) virus is endemic in Central and northern South America and in the southeastern USA, causing an acute, febrile vesicular disease in cattle, horses, and pigs. Sporadic VS epidemics occur in the southwestern states of the USA. Both of the major serotypes, VS-Indiana and VS-New Jersey, cause influenza-like illness in humans and are an occupational hazard to people handling cattle. The VS viruses comprise a complex of related serotypes and subtypes in the Americas, with related vesiculoviruses (family *Rhabdoviridae*) in Africa and Asia. Many of these viruses are transmitted horizontally and transovarially by phlebotomine sandflies, with evidence for infection of wild rodents and other small mammals. However, the role of these mammals in the epidemiology of VS viruses is unclear because they do not develop viremia. Grasshoppers have been shown to be susceptible experimentally, but their role as reservoirs or amplifiers in nature remains to be established.

Other Neotropical Viruses

Oropouche virus, a Simbu serogroup bunyavirus, causes epidemics, occasionally severe, or acute febrile disease with arthralgia and occasional aseptic meningitis in humans in the Brazilian and Peruvian Amazon as well as Surinam and Panama. During rainy season epidemics, the virus is transmitted by *Culicoides paraensis* biting midges. Enzootic maintenance cycles are believed to involve forest mammals and arboreal mosquitoes.

Mayaro (MAY) virus occurs epidemically in the Brazilian and Bolivian Amazon Basin, and has also been associated with human febrile disease in Surinam and Trinidad. In humans, the acute, nonfatal, febrile disease with rash is clinically similar to CHIK, an alphavirus to which it is antigenically and taxonomically related. MAY virus appears to be maintained in nature in a cycle similar to that of YF, with arboreal mosquito vectors and primate hosts, but also involving other mammals and birds.

Una virus is a close relative of MAY virus and causes human febrile disease also, but its natural history is not known. Una virus has been isolated from several mosquito species, and has been found at scattered sites from northern South America to Argentina. Antibodies have been found in humans, horses, and birds. Genetic analysis suggests that Una virus is maintained in discrete foci.

Rocio virus was first isolated from fatal human encephalitis cases during an explosive outbreak of acute febrile disease in coastal Sao Paulo State, Brazil in 1975, after which sporadic outbreaks have continued. This virus is an ungrouped flavivirus in the *Togaviridae* and is serologically related to Murray Valley encephalitis virus from Australia. The epidemiology is unclear but probably involves wild birds, and several mosquito species are suspected vectors.

Cowpox-Like Viruses

Cantagalo and related viruses are orthopoxviruses newly reported in Brazil. They can cause vesiculopustular lesions on the hands, arms, forearms, and face of dairy milkers.

Virus particles can be detected by either direct electron microscopy (DEM) in vesicular fluids and scab specimens or isolated in cell culture and embryonated chicken eggs. The epidemiological significance of these new vaccinia viral strains and their origins remains unknown.

Viruses Occurring in Europe

Tahyna (TAH) virus is widely distributed in Europe and has been reported in Africa. TAH virus produces an influenza-like febrile disease, with occasional central nervous system involvement. The virus is a bunyavirus of the California serogroup, in the *Bunyaviridae*. Like LAC virus, small forest mammals are TAH virus reservoirs, and the virus is horizontally and transovarially transmitted by *Ochlerotatus* mosquitoes. There are no effective control measures.

Omsk hemorrhagic fever occurs in a localized area of western Siberia. Disease can be severe, with up to 3% case fatality, and sequelae are common. This virus is a member of the TBE complex of the flaviviruses. The virus is epizootic in wild muskrats, which had been introduced into the area, and is associated with ixodid ticks. Muskrat handlers are at highest risk of infection. Water voles and other rodents are also vertebrate hosts of the virus. TBE virus vaccine is used in high-risk individuals to provide protection.

TBE virus is also a member of the TBE complex of flaviviruses. TBE virus has been classified into three subtypes: European, far eastern, and Siberian. Because recreation in wooded areas has increased in recent years, TBE has become the most frequent arthropod-borne disease in Europe. The virus occurs in deciduous forests in Western Europe from the Mediterranean countries, westward to France, northward to the Scandinavian countries, and eastward to Siberia. It is maintained in a transmission cycle involving small mammals and *Ixodes* spp. ticks. Human infection also occurs through the consumption of unpasteurized milk from infected cows and goats. Infection can be prevented by an inactivated vaccine and avoidance of tick bites.

Cowpox virus is an orthopoxvirus in the *Poxviridae*. It has a wide host range. Domestic cats are the most important source of human infection, transmitting the virus from wild rodent reservoirs to people. In addition to cattle, this virus has produced severe, generalized infections in a variety of incidental animal hosts in zoos and circuses, including elephants and large cats, which may die. Humans develop typical poxvirus lesions (vesicle and pustule formation), usually on the hands. Laboratory diagnosis (characterization of isolated virus) is required to differentiate cowpox from other nodule-forming zoonotic poxviruses such as orf virus, bovine papular stomatitis virus, and pseudocowpox virus, which are worldwide in distribution.

Viruses Occurring in Africa and the Middle East

Rift Valley Fever Virus

Rift Valley fever virus (RVF) is among the most serious arbovirus infections in Africa today. Repeated RVF epidemics in sub-Saharan Africa cause serious disease in small ruminant animals and humans. RVF disease has expanded its historical geographic range in the livestock-raising areas of eastern and southern Africa and into the Middle East (Saudi Arabia and Yemen) over the past 25 years, causing massive epidemics in Egypt, along the Mauritania–Senegal border and in Madagascar. A major outbreak in East Africa began in 2006 in northeastern Kenya, and spread into southern Somalia and Tanzania. Cattle, sheep, and humans are affected. Abortion storms with febrile disease and bloody diarrhea occur in ruminant animals, and mortality may be heavy in young stock. Most infected humans develop febrile disease, with prolonged convalescence. A few individuals develop more severe disease, with liver necrosis, hemorrhagic pneumonia, meningoencephalitis, and retinitis with vision loss. The human case–fatality rate is less than 1%. RVF virus is in the genus *Phlebovirus* of the *Bunyaviridae*. In sub-Saharan Africa, RVF virus is closely tied to its *Aedes* mosquito vectors. RVF vectors transmit the virus transovarially and horizontally. The virus persists in mosquito eggs laid around seasonally flooded pools and depressions. When these pools flood, the eggs hatch and infected mosquitoes emerge and begin transmission. The vertebrate reservoir hosts of RVF virus are unknown. Field and laboratory workers need to exercise caution to avoid becoming infected by exposure to the virus during postmortem examination of animals or processing materials in the laboratory. Both live, attenuated and inactivated vaccines are available for animals, but the unpredictability of scattered, sporadic RVF outbreaks across sub-Saharan Africa is a major obstacle for implementation of extensive, cost-effective vaccination programs.

Marburg and Ebola Viruses

The reappearance of epidemic Ebola disease in Kikwit, Democratic Republic of the Congo (formerly Zaire) in 1995 and Makokou, Gabon in 1996 again focused international attention on this hemorrhagic disease. Marburg and Ebola viruses have sporadically caused severe hemorrhagic fever in humans. Marburg virus, although of African origin, first appeared in laboratory workers in Germany who had handled cell cultures originating from African primates. Later, epidemics of severe hemorrhagic fever occurred in the Sudan and in Zaire, and Ebola virus was isolated. The first nonlaboratory epidemic of Marburg virus occurred in the Democratic Republic of the Congo from 1998 to 2000. A second, and more severe, outbreak

occurred in Uige Province of Angola from 2004 to 2005, when 329 of 374 infected people died (case–fatality rate of 88%). These viruses produce hemorrhagic shock syndrome and visceral organ necrosis, and have the highest case–fatality rate (30–90%) of the hemorrhagic fevers. These viruses, with their bizarre filamentous, pleomorphic morphology, belong to the family *Filoviridae*. They are presumed to be zoonotic, but their hosts in nature and mechanisms of transmission in the field have not been determined. Most of the Makokou, Gabon patients had very recently butchered chimpanzees. A variant of Ebola virus has been isolated from chimpanzees from Côte D'Ivoire, but since wild primates suffer severe disease, they are unlikely to be maintenance reservoirs. Nosocomial transmission of Marburg and Ebola viruses has occurred frequently; a high level of patient isolation and biosafety containment are essential to avoid hospital- and laboratory-acquired infection. Serologic diagnosis is accomplished by means of indirect immunofluorescence or enzyme-linked immunosorbent assay (ELISA) test, with antigen specificity confirmed by western blot. No vaccines or control measures are available.

Monkeypox Virus

Human monkeypox is a severe, smallpox-like illness. Monkeypox belongs to the genus *Orthopoxvirus* of the *Poxviridae*. Monkeypox virus (MPXV) is endemic in rodents in West and Central Africa, with the occurrence of sporadic human cases. The case–fatality rate in humans appears to be higher in Central Africa than in West Africa, raising questions about possible difference in virulence in these two large geographic areas. The largest epidemic of human monkeypox ever documented occurred in the Katako-Kombe area of the Democratic Republic of the Congo (formerly Zaire) in 1996–97, with over 500 people becoming ill and five deaths. Rodent-to-human transmission occurred, as did subsequent secondary human-to-human spread. Vaccinia is protective against infection, but its use has been discontinued with the eradication of smallpox. In 2003, monkeypox emerged for the first time in the Western Hemisphere and caused an outbreak in the United States (Midwestern states) affecting 37 people exposed to ill prairie dogs purchased from pet stores. The virus entered the US upon the importation of exotic rodents from Ghana (West Africa). Recent nucleotide sequence analysis demonstrated the existence of two genetically distinct variants of the virus, called the West African and Congo Basin clades. The strain that caused the US outbreak belonged to the West African clade.

Semliki Forest Virus

Semliki Forest (SF) virus caused an extensive epidemic of human disease in Bangui, Central African Republic, in 1987. SF virus is an alphavirus in the *Togaviridae*. It occurs across East, Central, and West Africa, and has been isolated from various mosquitoes and from wild birds. Antibodies have also been found in wild mammals. The SF virus maintenance cycle probably involves *Ae. africanus* mosquitoes and vervet monkeys.

Orungo Virus

Orungo (ORU) virus caused mild epidemic disease (fever, nausea, headache, and rash) in Nigeria. The virus occurs in a band across Africa from Uganda to Sierra Leone. It is probably mosquito transmitted, but the species that transmit it in nature are not known. Although the vertebrate reservoir hosts are unknown, wild primates have antibody and are suspected to be involved in virus maintenance.

Alkhurma Virus

Alkhurma virus (a variant of Kysanur Forest disease virus, family *Flaviviridae*, genus *Flavivirus*) is an emerging pathogen responsible for hemorrhagic fever in the Middle East. This virus was isolated from hemorrhagic fever patients in Saudi Arabia in 1995. Transmission can occur from tick bites, handling carcasses of infected animals, or drinking unpasteurized milk. The case–fatality rate is 25%.

Viruses Occurring in Asia

Influenza Viruses

Influenza viruses belong to the family *Orthomyxoviridae,* which consists of five genera: influenza A, influenza B, influenza C, Isavirus, and Thogoto viruses. Influenza A viruses are widely distributed in nature and can infect a wide variety of birds and mammals. Influenza A virus subtypes are classified on the basis of the antigenicity of their surface glycoproteins hemagglutinin (HA) and neuraminidase (NA). To date, 16 HA and 9 NA genes are known to exist. Of these genes, only three HA (H1, H2, and H3) and two NA (N1 and N2) subtypes have circulated in the human population in the twentieth century. During the last 100 years, the most catastrophic impact of influenza was the pandemic of 1918, also known as the Spanish flu (H1N1), which resulted in the loss of more than 500 000 lives in the United States and caused about 40 million deaths worldwide.

The ability of influenza viruses to undergo antigenic changes is the cause of ongoing significant public health concern. New subtypes emerge when human virus captures genes from animal influenza viruses via reassortment; an event that can occur when both virus types simultaneously infect a host (antigenic shift). The threat imposed by influenza virus has been further elevated with the recent introductions of avian influenza viruses into

the human population. Avian influenza viruses were initially considered nonpathogenic for humans. However, this perception has changed since 1997, when 18 Hong Kong residents were infected by an avian influenza virus of the H5N1 subtype that resulted in six deaths. Over the next few years, several other cases of direct avian-to-human transmission were reported, including the ongoing outbreak of highly pathogenic H5N1 influenza viruses in several Asian, African, and European countries. Migratory waterfowl – most notably wild ducks – are the natural reservoir of avian influenza viruses, and these birds are also the most resistant to infection. Domestic poultry, including chickens and turkeys, are particularly susceptible to epidemics of rapidly fatal influenza. Direct or indirect contact of domestic flocks with wild migratory waterfowl has been implicated as a frequent cause of epidemics. Live bird markets have also played an important role in the spread of epidemics. Viruses of low pathogenicity can, after circulation for sometimes short periods in a poultry population, mutate into highly pathogenic viruses. Quarantine of infected farms and destruction of infected or potentially exposed flocks are standard control measures aimed at preventing spread to other farms and eventual establishment of the virus in a country's poultry population.

Severe Acute Respiratory Syndrome

In February 2003, a new and previously unknown disease, severe acute respiratory syndrome (SARS), was reported to the World Health Organization (WHO). SARS originated in the province of Guangdong in southern China in November 2002 where it initially was thought to cause atypical pneumonia. However, within a short time the virus spread to Hong Kong, Singapore, Vietnam, Canada, the United States, Taiwan, and several European countries. A novel coronavirus (CoV) was identified as the etiological agent. The SARS-CoV affected more than 8000 individuals worldwide and was responsible for over 700 deaths during the first outbreak in 2002–03. For reasons unknown the SARS virus is less severe and the clinical progression a great deal milder in children younger than 12 years of age. In contrast, the mortality rate was highest among patients >65 years and can exceed 50% for persons at or above the age of 60 years. Farmed masked palm civets (*Paguma larvata*) and two other mammals in live animal markets in China were sources of SARS-CoV human infection. Three species of horseshoe bats (*Rhinolophus* spp.) are probable wildlife reservoirs in China.

Kyasanur Forest Disease

Kyasanur Forest disease (KFD) was first recognized in India in 1957, when an acute hemorrhagic disease appeared in wild monkeys and people frequenting forested areas. KFD has been slowly spreading in India. Human cases have increased from 1999 to 2005, with peak incidence in January and February. The cause of this increase is unknown. KFD virus is a member of the TBE complex of flaviviruses. The basic virus maintenance cycle involves forest mammals (primates, rodents, bats, and insectivores) and ixodid ticks, mainly *Haemaphysalis spinigera*. The virus can be isolated in mice and cell cultures, including tick cells. An inactivated vaccine provides some protection to people at risk of infection.

Japanese Encephalitis Virus

Japanese encephalitis (JE) virus is found in a broad area from far eastern Russia, northeastern Asia through China and Southeast Asia to Papua New Guinea and the Torres Strait Islands of Australia and westward into India. JE virus causes the greatest number of clinical human cases, thousands annually, predominantly in children. It produces encephalitis in humans and horses, and acute febrile disease with abortion in swine, an amplifying host. Herons and egrets are wildlife amplifying hosts. The virus is transmitted by *Culex* spp. mosquitoes. The over-wintering mechanism in temperate Asia is unknown. JE virus is a member of a complex of four related flaviviruses in the family *Flaviviridae*. Prevention of disease is mainly through vaccination of humans, horses, and swine. Insecticides and integrated pest control measures that include natural compounds (*Bacillus thurengiensis* toxins), larvicidal fish, and larval habitat modification have been successfully used in China. Use of pyrethroid-impregnated bed netting can also prevent transmission.

Chandipura

Chandipura virus is ubiquitous across the Indian subcontinent. It is a *Vesiculovirus* in the *Rhabdoviridae*. Chandipura has caused epidemics of febrile diseases, sometimes with encephalopathy. An outbreak occurred in 2004 with a case–fatality rate of 78.3% in children in India (Gujarat State). The virus is transmitted by *Phlebotomus* spp. Sergentomine sandflies and infects a variety of mammals. The virus has also been isolated in West Africa.

Nipah

Nipah virus (NiV) was first recognized in peninsular Malaysia in 1998, where it caused encephalitis and respiratory disease in commercially raised pigs, with transmission to humans in contact with them, with 40–76% case fatality. The virus was found in five species of giant fruit bats (*Pteropus* spp.) there and NiV was

isolated from partially eaten fruit. Subsequently, there were five NiV outbreaks recognized in Bangladesh, also associated with *Pteropus* bats. Transmission in Bangladesh was directly from bats, via contaminated fruit and date palm sap.

Viruses Occurring in Australia

Murray Valley Encephalitis Virus and Kunjin Virus

Murray Valley encephalitis (MVE) virus and the closely related Kunjin virus are flaviviruses that cause encephalitis, although Kunjin virus more commonly produces a nonencephalitic illness with polyarthralgia. MVE virus is endemic in avian species and is found in humans in northern Western Australia, the Northern Territory, and Queensland. MVE virus is endemic in northern areas of Western and Northern Australia, and in New Guinea. Kunjin virus occurs over a much wider area, including most of tropical Australia, Sarawak, Borneo, Papua New Guinea, and Saibai Island in the Torres Strait. There is some evidence that infection with these viruses is increasing in incidence. In northern Australia, MVE cases occur predominantly between February and July, corresponding to the end of the monsoon season, when the mosquito vector (*Culex annulirostris*) proliferates in flooded environments. MVE and Kunjin viruses are flaviviruses, family *Flaviviridae*, of the Japanese encephalitis complex. Kunjin is a subtype of WNV. RNA sequencing indicates that the Australian strains of MVE virus are similar to, but different from Papua New Guinea isolates. No vaccine is available. Control is achieved through application of larvicides.

Ross River Virus

Ross River (RR) virus has caused annual epidemics of febrile disease with polyarthritis and rash with most cases occurring in November through April. It is the most commonly reported arthropod-borne virus disease in Australia. RR virus occurs in all Australian states and territories, but is most commonly found in the northern states and coastal areas. Within the past two decades, RR virus has spread through several Pacific Islands in epidemic form and appears to have become endemic in New Caledonia. Convalescence can be long. RR virus is an alphavirus of the family *Togaviridae*. The enzootic maintenance cycles of RR virus in Australia are not well defined, but wild and domestic mammals appear to be the reservoir hosts, and the principal mosquito vectors are salt marsh *Aedes* spp. and freshwater *Culex* spp. In the Pacific Islands outbreaks, the virus was probably transmitted from person to person by *Aedes* mosquitoes.

Barmah Forest Virus

Barmah Forest virus is the second most common mosquito-borne disease in Australia. It causes subclinical and clinical infections in humans, including fever, myalgia, polyarthralgia, and rash. It is an alphavirus in the *Togaviridae*. The virus appears to be endemic in eastern Australia. It has been isolated from 25 different mosquito species in five genera. *Ochlerotatus vigilax* (previously known as *Aedes vigilax*), is considered a major vector. Its vertebrate hosts have not been established, although marsupials are suspected.

Control

On-going disease surveillance supported by rapid, reliable diagnosis is critical for recognition and control of zoonotic diseases. Serological diagnosis by means of ELISA tests, virus neutralization, and other tests, coupled with detection of the virus itself by virus isolation, immunohistochemistry, immunofluoresence, or PCR techniques are standard laboratory approaches, but are not available in all countries. Timely laboratory results must reach clinicians treating infected individuals and become incorporated into epidemiological databases and early warning systems to assure rapid response by public health authorities to control outbreaks appropriately.

Control of zoonotic virus diseases is accomplished by breaking the cycle of transmission. This is usually achieved by eliminating or immunizing vertebrate hosts, and reducing vector populations. Reduction of reservoir host populations is usually not accomplished because it is too expensive, not environmentally safe, and not technically or logistically feasible. However, there have been some notable exceptions. Bolivian hemorrhagic fever, caused by Machupo virus, was controlled by reduction of its rodent hosts through intensive rodenticiding. The principal vampire bat reservoir of rabies, *Desmodus rotundus*, is being controlled by the application of warfarin-type anticoagulants. Control programs like these have to be continuous to be effective. Their reduction or discontinuation results in host population recovery through reproduction and immigration, which may result in re-emergence of disease sweeping through the increasing, susceptible cohort.

Immunization of hosts is another control approach. Safe and effective rabies vaccines are being used for immunization of humans, domesticated animals, and some wildlife species. The human diploid cell vaccine is extremely effective, free of adverse effects, and widely available but at a cost too high for use in many developing countries. Safe, effective animal vaccines of cell culture origin are on the market. After some initial public resistance, raccoon populations in the eastern USA and wild foxes in Europe are being successfully immunized by means of an oral, vaccinia-vectored recombinant vaccine.

This experience illustrates the need for public understanding, in order to counteract fear of dispersal of a genetically engineered virus. However, vaccines will not be developed for many zoonotic viral diseases that affect relatively few people and are of very limited concern geographically.

Vector control is another promising but difficult area of zoonoses reduction or elimination. Insecticide application has become more problematic because both vectors themselves, as well as public opinion, have become more resistant to their use. Integrated pest management techniques, well developed for the control of many crop insects, along with the use of natural pesticides such as *Bacillus thurengiensis* toxin, offers promise for the effective, environmentally safe control of dipterous vectors. Control of tick vectors is likely to remain a problem for some time to come.

Emerging and Re-emerging Zoonoses

Ecological Change

Human disturbance has become a feature of nearly every part of the planet. All too often these disturbances create habitats that favor increases in populations of key hosts and vectors, with subsequent increased transmission of viral zoonoses. Nowhere are ecological changes happening more rapidly and profoundly than in the world's tropics. Conversion of tropical forests to agricultural ecosystems simplifies diverse ecosystems and provides either native or introduced host or vector species the conditions necessary to become more abundant, and sustain intensified virus transmission in areas where people live and work. In Africa, recent YF epidemics have been increasing dramatically in agricultural areas. Some agricultural irrigation development projects have created extensive vector breeding habitats, with an increase in mosquito-transmitted disease. The extensive dams constructed in Senegal were followed by epidemics of RVF, with numerous cases of disease in humans and small ruminant animals. The public health consequences of development projects must never be overlooked.

Global climate change will also bring ecological changes and shifts of human populations that will affect the occurrence of viral zoonoses. There is general consensus that changes in the global climate will happen with unprecedented speed. With those changes will come alterations in the geography of natural and agricultural ecosystems, with corresponding changes in the distribution of zoonotic diseases and the intensity of their transmission. It is clear that El Niño southern oscillation phenomena have increased rainfall, with resulting increases in rodent populations and occurrence of HPS in the Southwestern USA, and increased breeding sites for mosquito vectors of RVF virus in Africa. While it is not possible to predict accurately what the world will be like in 100 years or what zoonotic diseases are likely to be most troublesome, it is certain that things will be different, and constant surveillance will be essential to avoid serious problems or deal promptly and effectively with the ones that arise.

Movement of zoonotic viruses can result from the displacement of infected animals, contaminated animal products, and virus-carrying arthropod vectors. Pets, sport, laboratory, and agricultural animals are moving around the world as never before. Although international and national regulations have been established to prevent movement of infected individuals, it is not possible to test for all possible zoonotic viruses, and prevent them from crossing international boundaries. Moreover, significant numbers of animals of high commercial value move illegally. The importation of highly virulent Newcastle disease (ND) virus has been occasionally linked to smuggled birds.

Zoonotic viruses may be transported by movement of arthropod vectors, too. Just as the YF mosquito, *Ae. aegypti*, moved around the world in water casks aboard sailing vessels, mosquitoes are transported around the world in international commerce. Ships still transport mosquito vectors. The Asian tiger mosquito, *Ae. albopictus*, has become established in the Western Hemisphere after multiple introductions in eggs deposited in used tires. This mosquito is capable of transmitting YF, VEE, JC, and LAC encephalitis viruses. Perhaps of greater concern, modern transport aircraft have been shown to move vector mosquitoes internationally.

Human activity alters animal populations, contact between wild and domestic animals, and human–animal interactions, changing the occurrence of zoonotic diseases and the risk of infection to humans. For example, emergence of new influenza strains is related to the interaction of populations of people, pigs, and aquatic birds.

Social Change

Increasing human populations place great demands on the public health and other government services, especially in developing countries where needs for zoonoses diagnosis, control, and prevention are greatest and resources are most limited. Some preventive measures could be implemented by the people who live in the affected areas themselves, and at minimal costs, if they knew why and how they needed to do it. Public education and information is essential for control and prevention of zoonotic diseases; however, it takes more than civic action to deal with them. Delivery of public education, disease surveillance and diagnosis, and the technical materials and logistical support for control or preventive programs depend on national or international scientific and financial support. International technical cooperation and financial support are imperative.

Summary

Zoonoses are diseases transmissible from animals, other than humans, to people. Both new and old viral zoonoses are important in emerging and re-emerging virus diseases. Some zoonotic viruses occur worldwide, in a variety of ecological settings. Others are found only in limited ecologic and geographic foci. Important worldwide zoonotic viruses include rabies, hantaviruses, arenaviruses, yellow fever virus, chikungunya virus, Sindbis virus, Crimean-Congo hemorrhagic fever virus, and the sandfly fever viruses. In the Americas, common zoonotic viruses include the encephalitis viruses, Colorado tick fever virus, vesicular stomatitis, and others. Zoonotic viruses in Europe include Tahyna virus, the tick-borne encephalitis viruses, and cowpox virus. There are several zoonotic viruses in Africa and the Middle East, including Rift Valley fever virus, Marburg and Ebola filoviruses, monkeypox virus, Semliki Forest virus, Orungo virus, and Alkhurma virus. Zoonotic viruses occurring in Asia include the influenza viruses, SARS coronavirus, Kyasanur Forest virus, Japanese encephalitis virus, Chandipura virus, and Nipah virus. Zoonotic viruses occurring in Australia include Murray Valley encephalitis virus, Kunjin virus, Ross River virus, and Barmah virus. The human and animal health importance of these viruses and their control are discussed. Because rapid ecological change is occurring worldwide, additional zoonotic viruses will emerge.

SUBJECT INDEX

Notes

Cross-reference terms in italics are general cross-references, or refer to subentry terms within the main entry (the main entry is not repeated to save space). Readers are also advised to refer to the end of each article for additional cross-references - not all of these cross-references have been included in the index cross-references.

The index is arranged in set-out style with a maximum of three levels of heading. Major discussion of a subject is indicated by bold page numbers. Page numbers suffixed by T and F refer to Tables and Figures respectively. *vs.* indicates a comparison.

This index is in letter-by -letter order, whereby hyphens and spaces within index headings are ignored in the alphabetization. Prefixes and terms in parentheses are excluded from the initial alphabetization.

To save space in the index the following abbreviations have been used

CJD - Creutzfeldt–Jakob disease

CMV - cytomegalovirus

EBV - Epstein–Barr virus

HCMV - human cytomegalovirus

HHV - human herpesvirus

HIV - human immunodeficiency virus

HPV - human papillomaviruses

HSV - herpes simplex virus

HTLV - human T-cell leukemia viruses

KSHV - Kaposi's sarcoma-associated herpesvirus

RdRp - RNA-dependent RNA polymerase

RNP - ribonucleoprotein

SARS - severe acute respiratory syndrome

TMEV - Theiler's murine encephalomyelitis virus

For consistency within the index, the term "bacteriophage" has been used rather than the term "bacterial virus."

diagnosis 5:493
ecological change 5:494
as emerging diseases 2:95, 5:494
organ transplant infections 5:490
reservoir identification, phylogeny 4:128
social change 5:494
transmission 5:485
control 5:493
vectorial capacity 5:271
vector transport 5:494
see also specific diseases/disorders
see also specific viruses
Zoospore(s)
furovirus transmission 2:292
plant virus transmission 5:281
Zoster (shingles)
clinical features 5:253, 5:254*f*
complications 5:253
immunocompromised 5:253
postherpetic neuralgia 5:253
Ramsay–Hunt syndrome 5:253
epidemiology 5:252
age-relation 5:252, 5:252*f*
immunocompromised 5:252
etiology 5:252
virus reactivation 5:253
immunocompromised patients 5:252, 5:253
pathology 5:253–254
Zostera marina (seagrass), dsRNAs 2:112
Z protein
arenavirus assembly/budding 3:247
lymphocytic choriomeningitis virus replication/transcription 3:245–246
Z RING domain, arenavirus replication 3:245–246
Zta protein, EBV infection 2:166
Zucchini yellow mosaic virus (ZYMV) 5:290, **5:433–440**
biotechnological applications 5:439
classification 5:433
efficient vectors 5:437
epidemiology 5:436
spread 5:437
virus sources 5:436
evolution 5:439
genetics 5:439
geographical distribution 5:435
history 5:433
host range 5:435
infection *see below*
taxonomy 5:433, 5:434*f*
transmission 5:290
Aphis gossypii 5:436
via seed 5:436
weeds 5:436–437
ZYMV-NAT 5:436
use in transgenic plants 4:157, 4:158*f*
heterologous encapsidation 4:162
variability 5:438
vector relationships 5:436
Zucchini yellow mosaic virus (ZYMV) infection
control methods 5:437
cross-protection 5:437, 5:438*f*
genetically-modified resistant plants 5:438
prophylaxis 5:437
resistant cultivars 5:437
diagnostic methods 5:435
epidemics 5:290
symptoms 5:290, 5:434, 5:435*f*
synergism 5:435
Zygocactus symptomless virus (ZSLV) 4:311*t*
Zygocactus virus X (ZVX) 4:311*t*
Zygocin 5:307
structure 5:307
Zygomycota 4:419
retrotransposons 4:423, 4:424*t*
Zygosaccharomyces bailii
killer spectrum 5:307
phenotype inheritance 5:300
